The income reported by a corporation in any particular period is subject to a host of short-run economic and accounting factors that render it different from what would have been reported under "normal" conditions. Now if prices are related to normal rather than reported income, and if the short-run disturbances in reported earnings do not produce equiproportional disturbances in dividends, then a regression equation of the standard form will be biased in favor of dividend payout influences—a point touched upon by earlier writers but in a rather different context. To clarify, companies with above-normal earnings at a point of time will be characterized by both low price-earnings and dividend payout ratios, whereas companies reporting below-normal earnings will be characterized by both high price-earnings and high payout ratios.

The two conditions essential to the above argument are: (1) that dividends are a more stable time series than reported earnings; and (2) that the elasticity of shareholder expectations with respect to short-run income movements is less than unity. The existence of the first of these conditions has been proved quite conclusively by several studies of corporate dividend payout policy which show a rather slow adaptation of dividends to changes in reported earnings.<sup>10</sup> The second condition has, to our knowledge, not been proved, but in view of the great amount of background data available for the formulation of per-share income expectations, it seems reasonable to suppose that expectations are rather insensitive to those short-run movements in relative earnings which are unrelated to fundamental changes in long-run prospects for the economy, the industry, or the company.

#### *D. Income Measurement Errors*

The diversity of accounting procedures employed in estimating business earnings gives rise to consistent measurement errors that can bias regression results in favor of dividends on two counts. First, the simple fact that retained earnings are measured imprecisely exerts a downward bias on the coefficient for that variable (dividends are measured precisely, and therefore no such bias exists here). Since retained earnings are generally of the order of magnitude of one-third total earnings, and all of the probably sizable measurement error in total earnings affects the estimate of retained earnings, the downward bias in the retained earnings coefficient could be quite large.<sup>11</sup> Second, if both prices and dividends are geared to the economically "correct" value of earnings, then firms that employ accounting methods yielding relatively high reported earnings will be characterized by both low payout and low price-earnings ratios compared to the sample average, whereas those firms which maximize current deductions will show both high payout and high price-earnings ratios relative to the sample average. As a result, the retained earnings coefficient is again biased downward relative to the dividends coefficient.

Strictly speaking, the second of these accounting effects could logically have been discussed under the heading "omitted variables," above. However, the apparent lack of appreciation for the interrelation between accounting biases in reported earnings and the measured effect of dividends and retained earnings on share prices prompted this separate discussion as a means of drawing attention to what is

<sup>10</sup> See especially Lintner [11], and also Darling [2].

<sup>11</sup> See, e.g., Wold [18]. On the other hand, several analyses using average dividends and same relative importance to dividends in explaining stock prices, though this use of average retained income as explanatory variables (e.g., see Gordon [6]) attach about the averages would be expected to reduce the bias in the estimated influence of retained earnings.

potentially one of the most glaring weaknesses in those studies. In subsequent discussions of regression models and results, accounting limitations of the type described above will generally be incorporated in the "omitted variable" category.

It might be noted that the above discussion does not include accounting errors of the type that, because of fluctuations in certain costs such as write-offs, advertisement, research and development, etc., would result in random disturbances to an individual company's earnings. These are properly included in the "random income movements" category. We should also mention the problem of general over- or understatement of earnings. While the procedures we will use do adjust for differences among firms (which are consistent over time) in their reporting of earnings, they do not adjust for any general over- or understatement of earnings because of the formidable conceptual and statistical problems associated with identification and correction of this type error. We might emphasize, however, that if accounting estimates of earnings are generally less than those "estimated" by investors, the retained earnings coefficient will be biased upward.

#### *E. Least-Squares Bias*

Assuming that management and shareholder expectations are substantially independent, it is entirely plausible that a price-earnings ratio which is regarded as high by management will result in external stock financing and high payout, while capitalization ratios regarded as low will result in heavier reliance on internal financing and consequently low payout. Moreover, a similar result would occur if management were motivated only by a desire to maintain dividend-price ratios close to the average for the industry.

If these market relationships are reflected in cross-section data, the standard regression equation will yield results biased in favor of dividend payout because it assumes one-way causality between dividends and prices. That is, the equation fails to take account of the fact that dividend payout differences are, at least in part, the result rather than the cause of differences in price-earnings ratios. Resolution of this problem of dual causality requires the use of a complete model employing both demand and supply schedules for dividends.

## *II. Regression Models*

The problem of omitted variables could, of course, be directly handled by expanding the regression equation to include these variables. However, measurement of such slippery concepts as subjective risk evaluation, profitability of investment opportunities, sources of expected future financing, and accounting differences is both difficult and subject

to large error. Indirect approaches thus seem particularly attractive.

Theoretically speaking, continuous cross-section techniques are the most appealing of these approaches. If the separate effects on price of all omitted variables are aggregated, and this composite ("company" or "firm") effect given the designation  $F_i$ , then the basic regression equation (1) can be modified as follows:

$$(2) \quad P_{it} = a_i + b_i D_{it} + c_i R_{it} + F_i + e_{it}.$$

The assumption implicit in this equation is that firm effects, which cannot of course be measured directly, are both additive and constant over time. Such firm effects include those relevant to investor assessment of both profit prospects and risk, only some of which (e.g., size of firm and past trend and variability in book earnings) could alternatively be measured directly. Now if an identical equation is written for an earlier time period, and this last equation is then subtracted from the one above, the following result is achieved:

$$(3) \quad \begin{aligned} P_{it} - P_{i(t-1)} = & a_i - a_{i-1} + b_i D_{it} - b_{i-1} D_{i(t-1)} + c_i R_{it} \\ & - c_{i-1} R_{i(t-1)} + e_{it} - e_{i(t-1)}. \end{aligned}$$

The  $F_i$  do not appear in this equation, so the coefficients on dividends and retained earnings ought to be free of the bias due to firm effects.

Despite its theoretical appeal, this procedure runs into two complications: (1) in this particular application the error terms in the continuous cross-section difference equation become quite large; and (2) period-to-period movements in the variables can contain random elements and serial correlations that greatly impair the meaning and reliability of the coefficients.<sup>12</sup> The random movements in earnings are much more likely to be reflected in retained earnings than in dividends or in stock prices, depressing the apparent influence of retained earnings on stock prices. Moreover, the firm effects are more likely to be multiplicative than additive, and continuous cross-section techniques pose special problems in the multiplicative case. Consequently we feel other approaches are more promising for our purposes, at least at this stage of development of continuous cross-section techniques. In connection with these other approaches, we will henceforth assume a multiplicative relationship for the firm effects.

Thus suppose

$$(4) \quad F_{it} = f_i E_{it}$$

where  $f_i$  is now the firm-effect "multiplier" and  $E$  is per-share earnings.

<sup>12</sup> These complications can be avoided in part by the application of this type of cross-section difference equation to group rather than individual firm data, a procedure which has not been utilized previously and which we plan to experiment with.

The aggregate firm effect ( $F_{it}$ ) for any firm is assumed proportional to its per-share earnings, but the factor of proportionality ( $f_i$ ) differs among firms. If it is tentatively assumed that earnings payout effects are negligible, then

$$(5) \quad P_{it} = (k_i + f_i)E_{it},$$

where  $k_i$  is the average price-earnings ratio for the sample. Making the additional assumption that the  $f_i$  are constant over any two adjacent time periods:

$$(6) \quad f_{it} = f_{i(t-1)} = \frac{P_{i(t-1)}}{E_{i(t-1)}} - k_{t-1} = (P/E)'_{i(t-1)}.$$

Therefore, under the stated assumptions, firm effects can be held constant by introducing into the regression equation a variable  $[(P/E)'_{i(t-1)}]$  which measures individual deviations from the sample average price-earnings ratio in the previous time periods, i.e.,

$$(7) \quad P_{it} = a + bD_{it} + cR_{it} + d(P/E)'_{i(t-1)} + e_{it}.^{13}$$

In this equation (as well as in the continuous cross-section model) firm effects include the profitability of investment opportunities as assessed by the market.

The problem of least-squares bias can be handled by specifying a complete model including a dividend supply function as well as the customary price relation. For instance, let

$$(8) \quad P_{it} = a + bD_{it} + cR_{it} + d(P/E)'_{i(t-1)}$$

be the relation determining price; and let

$$(9) \quad D_{it} = e + fE_{it} + gD_{i(t-1)} + h(P/E)'_{i(t-1)}$$

be the dividend supply equation (error terms have been omitted). The dividend supply equation is developed by adding to the best type of relationship developed by previous writers<sup>14</sup> (which stresses the importance of past dividends on current dividends) a variable permitting the firm to adjust its current payout to past market valuation of its future earnings. The system is completed by the identity:

$$(10) \quad E_{it} = D_{it} + R_{it},$$

<sup>13</sup> In the regressions fitted subsequently,  $\{E\}_{i(t-1)}$  is used instead of  $\{E\}'_{i(t-1)}$  for statistical reasons. In these regressions, annual data are used as measures of the variables involved, though it can be argued that, at least for earnings, an average over a number of years might be preferable. While this was not tested, it might be pointed out that the use of such averages in another context did not affect the results significantly (see footnote 11) and that the assumed constancy of the firm effects becomes more tenuous the longer the period covered. Another approach to holding firm effects constant is to substitute equation (6) in equation (5), which results in equation (12), except that theoretically for this purpose the  $P_{i(t-1)}$  term in equation (12) should be multiplied by the ratio of  $E_{it}$  to  $E_{i(t-1)}$ .

<sup>14</sup> See Lintner [11].

where  $E_{it}$  may be considered exogenous but, of course, not  $D_{it}$  or  $R_{it}$ . Solving these equations (8), (9), and (10) we have:

$$(11) \quad P_{it} = [a + e(b - c)] + [c + f(b - c)]E_{it} + [g(b - c)]D_{i(t-1)} \\ + [d + h(b - c)](P/E)'_{i(t-1)}.$$

After obtaining the regression coefficients of equations (9) and (11) in the usual manner, the coefficients of equation (8) can be derived and are theoretically free of bias due to effects of price on dividend supply.

Turning to the problem of random income movements, the argument here, it will be recalled, implies that short-run changes in income evoke relatively small short-run changes in relative price. Thus, an equation of the form

$$(12) \quad P_{it} = a + bD_{it} + cR_{it} + dP_{i(t-1)}$$

in which previous expectations, measured by  $P_{i(t-1)}$ , as well as current dividend and earnings experience, are assumed to determine current price is consistent with this assumption about price behavior. The  $b$  and  $c$  coefficients in this equation measure the extent of short-run price adjustment to short-run changes in dividends and earnings retention, respectively. Long-run values of these coefficients can, after correcting  $d$  for movements in the general market price level, be obtained by dividing each through by  $1 - d$ , provided it can be assumed that  $d$  measures only the influence of past expectations on current expectations. One of the additional merits of this equation is that lagged price to some extent also holds constant any firm effects that exist; as a result, however, long-run coefficients computed by this method may be somewhat in error.

A more direct approach to the problem of short-run earnings movements lies in the "normalization" of those earnings. Other authors have attempted this—usually by use of centered or weighted averages—but we feel that these methods are somewhat less satisfactory than available alternatives. A simple average of earnings over, say, a three-year period may still contain large short-run components (relative to future expectations) if the adjustment process is slow. The same comment also applies to weighted averages and, in view of the relatively high weight usually given to current earnings, this technique may be even less satisfactory than the use of a simple average.

Of several alternatives available for earnings normalization, an approach that seems especially promising is one in which market estimates are employed. To illustrate, assume that price and dividends are always taken as "normal," and that short-run earnings abnormalities sum to zero over the sample of companies in question (the latter being a reasonable assumption for most industries over most periods if we avoid

major cyclical disturbances). Thus, the dividend-price ratio is assumed to be always normal but the earnings-price ratio is subject to short-run fluctuations. Variations about trend values of the ratio  $(E/P)_{it}/(E/P)_{kt}$  are, by assumption, due solely to short-run components of the  $i^{\text{th}}$  company's earnings, because the average earnings-price ratio for the sample  $[(E/P)_{kt}]$  is defined to be free of earnings disturbances. Examination of the scatter diagrams of the time-series behavior of this "relative earnings yield" ratio failed to indicate any reason for assigning anything other than a linear equation to the underlying time trend. Therefore, on an empirical basis,

$$(13) \quad \frac{(E/P)_{it}}{(E/P)_{kt}} = a_i + b_{it} + e_{it}.$$

Now normal value of company earnings-price ratios can be computed as follows (the superscript  $n$  denoting normalized value):

$$(14) \quad (E/P)_{it}^n = [a_i + b_{it}](E/P)_{kt}.$$

Having obtained a normalized value of the earnings-price ratio, normalized earnings are found by simply multiplying this ratio by per-share price. Normalized retained earnings are then obtained by subtracting observed dividends from normalized earnings.

The assumptions underlying this approach can, of course, be questioned—dividends do react to year-to-year fluctuations in earnings; price does contain speculative components; and earnings fluctuations may not sum to zero over the sample. However, dividends are likely to react only to fluctuations in earnings regarded as relatively permanent. Moreover, averaging price over a year should remove most relative speculative components of individual share prices since, in theory, arbitragers can be expected to hold these to short duration. Any error attaching to the assumption that sample average earnings are normal is likely to be small and thus its effect on the regression equation will also be small.<sup>15</sup> Nevertheless, prices, as we measure them, probably do contain individual speculative components of small magnitude. Thus normal earnings computed from measured prices will contain errors of the same relative magnitude and direction as those contained in price, so that some small bias is probably introduced in favor of the retained earnings coefficient.

All of the statistical models presented earlier can, of course, be modified to specify normalized values of those variables in which earn-

<sup>15</sup> This earnings normalization procedure was developed in Mr. Puckett's forthcoming Ph.D. dissertation, and the validity of its assumptions are subjected to critical evaluation in that work. Alternative methods of earnings normalization—for instance, by derivation of a normal dividend payout ratio—are also presented.

ings fluctuations play a distorting part. The regression results presented later embody two such modifications.

Finally, the influence of dividend payout on price can be subjected to time-series analysis. For instance, the above equations relating relative earnings yield to time can be compared with regression equations of the following form,

$$(15) \quad \frac{(D/E)_{it}}{(D/E)_{kt}} = a_i + b_{it} + e_{it},$$

to ascertain if changes over time in relative earnings-price ratios are consistently associated with changes in relative dividend payout ratios—and, if so, the nature of the association. This procedure, it might be noted, involves none of the assumptions necessary for derivation of normalized earnings and, hence, constitutes an independent check on their validity. Many other time-series tests of the relative importance of dividends and retained earnings are also possible.

### III. Regression Results

For most of our statistical analysis we worked with five industry samples, viz., chemicals, electronics, electric utilities, foods, and steels, in each of two years, 1956 and 1958. The industries were selected to permit a distinction to be made between the results for growth and non-growth industries and to provide a basis for comparison with results by other authors for earlier years. Both cyclical and noncyclical industries are covered. Ready accessibility of data and resource availability were also factors both in industry and year selection. An attempt was made to conform to a fairly narrow definition of the industries chosen so that the sample companies would be reasonably homogeneous in industrial composition.<sup>16</sup> The periods covered include a boom year for the economy when stock prices leveled off after a substantial rise (1956) and a somewhat depressed year for the economy when stock prices, however, rose strongly (1958). Originally we had intended including several earlier years as well, but it was not feasible to do this systematically.

Table 1 presents the usual simple linear relationships between average prices and dividends and retained earnings to show with the data we are using the kinds of results typically obtained, and to provide a basis of comparison with alternative regression models. In this analysis, we find the customary strong dividend and relatively weak retained earnings effect in three of the five industries—i.e., chemicals, foods, and steels. In these three industries, there is little evidence of any significant shift in the relative importance of retained earnings from earlier years as a result of increasing market emphasis on growth.<sup>17</sup> While these re-

sults may not be altogether surprising for steels and foods, they seem highly questionable for chemicals, which was probably regarded as a growth industry in this period. Even for steels and foods the magnitude of the difference between the dividend and retained earnings coefficients seems implausible.

The fact that electric utilities show fully as high a coefficient and electronics a higher coefficient for retained earnings than for dividends is in closer agreement with what might be expected. Unfortunately, we know of no earlier results for electronics that can be used as a basis of comparison.

For electric utilities, there are two earlier analyses that can be compared with our results, though the forms of the relationships used are somewhat different. The first, by Morrissey [16], relates the earnings-

price and dividends-price ratios separately to the dividend payout ratios for each of the years 1950-57 and finds that the payout ratio in this industry did affect stock prices significantly in the early part of this period (with higher prices associated with higher payout) but very little in the latter part of this period. Moreover, this study found a steady reduction in the importance of the payout ratio from year to year and some evidence that the direction of its effect had changed by the end of the period, i.e., that higher payout may have been associated with lower prices for given earnings by 1957. These results are consistent with investors' changing evaluations of the growth potential of electric utilities and, for the end of the period covered, with our results in 1956 and 1958. However, the second earlier analysis referred to, which derives a logarithmic relation between the ratio of stock prices to book value and both the ratio of earnings to book value and the payout ratio, yields a different result for utilities in early 1955 showing a positive relation between the price to book ratio and payout.<sup>18</sup>

A recomputation of the electric utilities regressions in Table 1 utilizing logarithms for all the variables again points to a higher dividend than retained earnings effect, unlike the result obtained in the linear form.<sup>19</sup> It is not possible to choose conclusively between the linear and logarithmic results on statistical or a priori grounds. The logarithmic relations do reduce the problem of regression weights referred to earlier (with a correlation between these weights and investment quality exaggerating any regression bias due to a correlation between quality and dividend payout). However, so do both the ratio relations discussed above and the more complex linear relations in subsequent tables, all of which give the same type of results for the electric utilities as the simple linear relations. Moreover, the ratio and linear regressions, unlike the logarithmic relations, can handle satisfactorily very small and negative retained earnings. We feel that the major difference between the logarithmic and nonlogarithmic regressions may be due to the differing degrees of bias in the regression coefficients produced by short-run income disturbances, and we shall attempt to hold these constant in some of the following statistical analyses.

To summarize the results so far, they provide a little more evidence than has existed heretofore that in growth industries (chemicals, electronics and electric utilities) more weight relatively is given to retained earnings than in nongrowth industries (steels and foods), but the evidence is not uniform (chemicals) and for one of the two remaining industries (electric utilities) depends partly on the mathematical form of the regression used. In any event, for three of five groups including one

<sup>18</sup> See Durand [3]. It is not clear whether utilities other than electric are included.

<sup>19</sup> The only other industry regressions which were recomputed were for chemicals and here the logarithmic results were quite close to the linear results.

presumably growth industry, we find again the same peculiar result obtained by our numerous predecessors using similar kinds of analysis—i.e., a predominant dividend effect.

One simple approach to holding firm effects constant (and in the process to reduce the problem of regression weights) is to add a lagged earnings-price ratio to the equations in Table 1. The results presented in Table 2 again indicate that dividends have a predominant influence on stock prices in the same three out of five industries but the differences

between the dividends and retained earnings coefficients are not quite so marked as in the first set of regressions. The dividends and retained earnings coefficients are closer to each other for all industries in both years except for steels in 1956, and the correlations are higher, again except for steels.

These new regressions, however, are not too satisfactory for a variety of reasons, of which the potential bias arising from short-run income disturbances is probably the most important. Moreover, an additional possible source of bias involves another question that was raised previously—i.e., the influence of stock price on dividend payout levels set by managements. Table 3 presents for four industry groups in 1958

the relevant dividend supply equations and the derived price equations obtained from the solution of the complete model, which contains three equations—the price equation (8), the dividend supply equation (9), and the identity (10). The derived price equations show no significant changes from those obtained from the single equation approach in Table 2, reflecting the fact that stock price, or more accurately the price-earnings ratio, does not seem to have a significant effect on dividend payout. On the other hand, it might be noted that, in three of the four cases tested, the retained earnings effect is increased relatively,

with no change in the fourth case. These results suggest that price effects on dividend supply are probably not a serious source of bias in the customary derivation of dividend and retained earnings effects on stock prices, though such a bias might be masked if the disturbing effects of short-run income movements are sufficiently great.

To provide some direct evidence on the potential bias arising from short-run income movements, the standard linear equation in Table 1 can be modified to include a lagged price variable which allows for slow short-run adjustment in prices to current levels of income. As noted earlier, to some extent the lagged price variable also holds firm effects constant; it also minimizes the problem of regression weights. These results are presented in Table 4.

Examination of this table shows that retained earnings receive greater relative weight than dividends in the majority of cases. The only exceptions are steels and foods in 1958. In all three groups which would normally be considered growth industries (chemicals, electronics, and utilities) the retained earnings effect is larger than the dividend effect for both years covered. For the other two industries (steels and foods) there no longer seems to be any significant systematic differences between the retained earnings and dividend coefficients, though there is some suggestion that dividends became relatively more attractive in 1958 than in 1956, which may not be surprising in view of the possible change in outlook for these industries at that time. This set of regressions has a number of attractive features apart from eliminating the customary anomalous result for dividends and retained earnings. The correlation coefficients as a whole have been substantially improved. The regression coefficients of the constant terms are in general close to zero, which is in accord with theoretical expectations, and the magnitudes of the lagged price coefficients seem generally sensible. Interestingly also, relationships for earlier years (1949, 1950, and 1952), identical in form to those in Table 4, show relatively weaker retained earnings effects than in the later years, a finding fully in accord with the changing emphasis on growth characteristics of stocks in this period.<sup>20</sup>

However, the regressions in Table 4 also have numerous limitations, including the possibility that the lagged price variable may serve in part as a proxy for dividends. Perhaps as a consequence, the regressions exhibit such undesirable properties as frequently negative dividend coefficients (though these are generally insignificant) and large standard errors for both dividends and retained earnings. These regressions, nevertheless, do seem to point to the weakness of the response of price to short-run changes in earnings, and to the fact that this response is not greatly affected by whether such changes in earnings are paid out

<sup>20</sup> It was possible to derive such regressions in the earlier years for all industry samples except the electronics.

as dividends or retained. There is some indication that retained earnings are more important than dividends (particularly for growth industries) but in half the cases neither the short-run dividend nor the retained earnings coefficient is significantly different from zero.<sup>21</sup>

Another and independent approach to the problem of short-run income movements which was described earlier is to normalize earnings by deriving time-series regressions of the form of equation (13) for each of the *i* companies in the *k*<sup>th</sup> industry group, and obtaining normalized retained earnings by subtracting dividends from normalized earnings, i.e., from  $[a_i + b_i d] (E/P)_{it} \cdot P_{it}$ . This normalization procedure was based on the period 1950-61, and prices were then related to dividends and normalized retained earnings for chemicals, foods, and steels in 1956 and 1958, with the results presented in Table 5. Subsequently, the

<sup>21</sup> Logarithmic regressions otherwise identical in form with those in Table 4 were computed for chemicals and electric utilities and showed very similar results to the linear relations.

prior year's normalized earnings-price variable was also added to hold firm effects constant; these results are presented in Table 6.

A comparison of the results in Tables 5 and 6 with the corresponding regressions in Tables 1 and 2 shows the significant role of normalized earnings in eliminating part of the usual understatement of the relative importance of retained earnings, while a comparison of Tables 5 and 6 again indicates the similar role of a device (in this case, the normalized price-earnings ratio) holding firm effects constant. An examination of Table 6 shows that for the industry groups covered most, but not all, of the differences between dividend and retained earnings coefficients disappear when earnings are normalized and firm effects held constant. Similar regressions were not computed for the electronics sample since a sufficiently long time period for earnings normalization was not available, or for the utilities sample since a different and more satisfactory sample is being analyzed separately by one of the authors. However, it might be noted that for this somewhat different (and somewhat larger) sample of electric utilities, normalizing earnings and holding firm effects constant reduce the dividend coefficient slightly and increase the retained earnings coefficient fairly markedly.

The results of Table 6 seem considerably more plausible to us than the usual findings for foods and steels, suggesting that in these industries a somewhat (but not drastically) higher investor valuation may be placed on dividends than on retained earnings within the range of pay-

out experienced so that management might be able to increase prices somewhat by raising dividends.<sup>22</sup> However, the regressions for chemicals in the table, though more satisfactory than those customarily obtained, do not seem quite so plausible since they imply the same type of result as for foods and steels.

A more detailed examination of our chemicals sample disclosed that the results obtained largely reflected the undue regression weighting given the three firms with prices deviating most from the average price in the sample of 20 firms. If these three firms are omitted, the results are changed substantially. As Table 7 indicates, retained earnings now become somewhat more important than dividends as a price determinant (again within the range of payout experienced).

In view of the possible bias in favor of the retained earnings coefficient that may be introduced by the earnings normalization procedure adopted, it was considered desirable to compare the time-series behavior of the relative earnings yield ratios previously discussed, i.e., equation (13), with that of relative dividend payout ratios obtained by deriving time-series regressions of the form

$$\frac{(D/E)_{it}}{(D/E)_{it}} = a_i + b_{it}$$

over the same time period. In view of resource limitations, this was done

<sup>22</sup> In this connection, it might be noted that foods and steels are characterized by lower payout than chemicals.

only for chemicals, which is considered the industry for which the customary results are most in question. The results in Table 8 show that in 12 out of 20 cases the time-slope coefficients for the relative earnings yield and relative payout regressions have the same sign, while in eight cases they are of opposite sign. This suggests that as relative payout increases, relative earnings yield increases somewhat more often than otherwise. In other words, the price-earnings ratio may have some tendency to move inversely to the payout ratio in contrast to the customary assertion of a direct relation. The correlation between the two slope coefficients is not very high but is significant ( $\bar{R}^2 = .543$ ). This is fairly strong evidence that the customary results are invalid, since the comparison of trends in relative yield and relative payout over time largely avoids both problems of short-run income fluctuations and problems of consistent firm effects. However, it should be noted that one difficulty may remain. If relative earnings yield goes down (i.e., relative price-earnings go up) because of a higher prospective rate of return on new corporate investment, the relative payout may go down because lower payout is associated with higher profit prospects, but the decline in payout would have no causative relation to the decline in yield. On the other hand, the customary finding that investors pay a premium for dividends as against retained earnings in the market even when the profitability of corporate investment opportunities is not held constant would still be invalidated.

#### IV. Some Concluding Remarks

Our analysis suggests that there is little basis for the customary view that in the stock market generally, except for unusual growth stocks, a

dollar of dividends has several times the impact on price of a dollar of retained earnings. There is some indication that in nongrowth industries as a whole, a somewhat (but only moderately) higher investor

valuation may be placed on dividends than on retained earnings within the range of payout experienced, but that the opposite may be true in growth industries. To the extent that this conclusion is valid, it is possible that management might be able, at least in some measure, to increase stock prices in nongrowth industries by raising dividends, and in growth industries by greater retention. However, the evidence that such possibilities exist to any important degree is rather tenuous, and there is no convincing indication of widespread management irrationality or irresponsibility in payout policy.

Unfortunately, the analysis we have carried out is limited not only in coverage of industries and time periods, but also in the linearity assumed. While the latter restriction can be justified on the grounds that a major objective was to question as expeditiously as possible the customary—and to us implausible—results obtained from similar mathematical forms, our results do not go very far in indicating what payout

ratios are regarded as optimal by investors for various types of stocks with different profitability of investment opportunities, risk, sources of financing, etc., or even in indicating whether an optimal ratio exists which to some extent is independent of profit prospects. Thus it would not surprise us if investors as a rule prefer at least a small nonzero (and preferably a stable or rising) payout, even at the cost of foregoing otherwise desirable investment. However, the further study of optimal ratios, while relatively simple in theoretical terms, involves much more complicated empirical analysis than has been attempted here.

## THE INTEGRATION OF CAPITAL BUDGETING AND STOCK VALUATION

By EUGENE M. LERNER AND WILLARD T. CARLETON\*

It is widely recognized that a corporation's cost of capital cannot be determined until an analysis is made of how the market values the firm's common stock [5, p. 423] [6, p. 143]. There is, however, no widely accepted theoretical apparatus linking the market valuation of common stock to a corporation's investment-opportunities schedule, dividend payout function, and capital structure.

It is the position of this paper that a fundamental reason for the current stalemate over the theoretical apparatus is the single-equation nature of recent capital-budgeting and security-valuation models [3] [7] [11]. Since one equation can determine at most one unknown, manipulation of these models has, for the generation of results, necessitated a variety of *ad hoc* restrictions to reduce each equation to a relationship between *two* variables only—as, for example, between share price and capital structure.<sup>1</sup> Two consequences emerge: (a) Since there is no consensus, such restrictions tend to be different. (b) More importantly, such variables as share price, capital budget, dividend payout, and capital structure are in the real world jointly determined, and the suppression of this dependency unnecessarily limits the relevance of any theoretical results. That is, whether the problem is simply simultaneous determination of all the variables or maximization of one (e.g., share price) subject to one or more constraints, enumeration of the relevant relationships contained in the budgeting-valuation nexus must be explicit.

In this paper we depart from the single-equation convention and explicitly introduce two equations: an investment-opportunities (or capital-budgeting) schedule and a stock-valuation equation. Under reasonable assumptions these two equations are shown to determine

\* The authors are, respectively, associate and assistant professor of finance at New York University, Graduate School of Business Administration. They wish to express their appreciation to Arnold Sametz and the members of the Investments Workshop for many helpful comments and criticisms, and to Howard Hendrickson who assisted in the design and execution of the figures.

<sup>1</sup> For example, see Lintner [7, pp. 250-51]. In order to generate the conclusion that investors will be indifferent to substitutions between elements in a corporation's time vector of dividends, it is necessary for Lintner to assume (among other things) given time vectors of earnings, capital budgets, and market discount rates.

simultaneously a corporation's internal rate of return, the percentage of earnings that it retains and the percentage that it distributes in dividends, and the price of its common stock. Furthermore, if the stock-valuation equation is treated as the corporation's objective function and the capital-budgeting equation as an internal constraint, we show that a unique maximum price can be found as a tangency solution.

The article falls into three major parts. Section I analyzes and modifies in two respects the stock-valuation model made popular by Myron Gordon in his *The Investment, Financing and Valuation of the Corporation* [3]. The Gordon model treats the price of a corporation's common stock as the present value of the expected future dividends, discounted at some given rate,  $k$ . Under the condition that the firm engages in no outside financing, retained earnings are reinvested by definition, so that a fixed relationship between dividend payout and capital budget emerges. A major difficulty of this model is that it generates unacceptable results when it is used as the sole determinant of the retention (hence, payout) rate which maximizes the value of the common stock. For example, the conclusion is reached that the corporation should retain and reinvest until the point at which the market value of stock equals book, or asset, value. The reason for anomalies of this sort is shown to be the implicit suppression of the mutual interaction within the firm of rate of return and size of capital budget. When a price map is drawn illustrating the substitutability of rate of return and dividend payout for shareholders at a given discount rate, the need for further specification of shareholder and corporation behavior becomes manifest. However, it is shown that even when  $k$  is treated as an increasing linear function of expected growth (in recognition of the growth-stock paradox) and the corporation's capital structure is formally introduced into the price model, the problem of what capital budget maximizes share price remains indeterminate.

Section II introduces an investment-opportunities schedule, positing the traditional inverse relationship between capital-budget size and internal rate of return. It then becomes obvious that there are two sets of rate of return and retention-rate expectations, one for the corporation and one for the shareholders. Under the necessary equilibrium condition that these two sets of expectations be equal, share price, dividend payout rate (and by construction, retention rate and capital budget), and internal rate of return are simultaneously determined. Finally, we demonstrate that there is a unique maximum share price attainable at some point along the corporation's investment-opportunities schedule. The more important implications of this tangency solution are: (1) a firm should not in general invest until internal rate of return equals the market discount rate; (2) most capital-budgeting "rules of thumb"

are likely to be suboptimal; and (3) the consequences of changing the dividend payout rate depend upon whether the firm is operating above or below the point of tangency.

Finally, in Section III the obtained results are evaluated in an equilibrium economics context, subject to amendment in a dynamic framework. In particular, the implied prescription that the corporation adopt shareholders' risk preferences is not unreasonable when the problem of disappointed expectations is suppressed (as is necessary in comparative statics). Such a decision rule might need to be modified for a dynamic world. Also, the introduction of capital structure as a variable to be determined is shown to require another equation, perhaps linking capital financing to dividend payout. The most reasonable context in which to do this may turn out to be an adjustment model in which expectations are generated over time.

### I. *The Stock-Valuation Equation*

#### *The Gordon Model*

The basic ingredients of any stock-valuation formula include: the particular stream of returns which is to be capitalized plus any time-dependent characteristics, such as a growth rate, that the stream possesses; the capitalization period (or investor time horizon); and the discount rate, or function. Academic debate over the proper definition of these ingredients has been exhaustive in recent years without being conclusive. The unfortunate fact is that normative results for corporate management depend rather strongly upon what definitions are adopted—whether the investor horizon is short-run or essentially infinite, for example. Rather than entering this terminological debate, we simply choose as a point of departure Myron Gordon's stock-valuation model [3, Ch. 4], which is a particularly well-developed and internally consistent approach to the valuation problem. Gordon defines investors' returns to be a growing stream of dividends, the market horizon as infinite, and the discount rate as a function, variously specified. He assumes no outside financing in his basic model, so that the establishment of a dividend payout automatically determines the capital budget as retained earnings.

Proceeding formally, assume that the corporation's dividends are expected to grow at a rate proportional to their present level,

$$(1.1) \quad \frac{dD}{dt} = gD,$$

and that, at time 0, the dividend payment is  $D_0$ . (Because new equity financing is excluded,  $D$  in the subsequent development can be thought of in terms of either a per-share or a firm basis.)

Assume further that the value of a dividend stream decays at a rate proportional to its existing value,

$$(1.2) \quad \frac{dV}{dt} = -kV,$$

and that at time 0 the value of the stream is  $V_0=1$ ;  $k$  can be taken as the market rate of discount.

The solutions of these two differential equations are

$$(1.1') \quad D_t = D_0 e^{gt},$$

$$(1.2') \quad V_t = V_0 e^{-kt}.$$

Since the price of a share is equal to the present value of the stream of all future dividends, equations 1.1' and 1.2' can be combined as follows:

$$(1.3) \quad P_0 = \int_0^{\infty} D_0 e^{gt} e^{-kt} dt$$

where  $t=0$  is now the date of valuation. A necessary condition for performing the integration is that  $k > g$ , for if  $k \leq g$ , the value of the expression equals infinity, the well-known problem of growth-stock valuation [2].

Solving equation 1.3 yields

$$(1.4) \quad P_0 = \frac{D_0}{k - g}.$$

The assumption that dividends grow at a constant rate is itself based on two assumed expectations; first, that the corporation is expected to earn a constant rate of return,  $r$ , on assets; and second, that the corporation is expected to retain a constant percentage,  $b$ , of its income. With the assumption that there is no debt in the capital structure of the corporation and that all growth of future dividends must come via retained earnings, equation 1.4 can then be rewritten in the form that Gordon gave it:

$$(1.4') \quad P_0 = \frac{(1 - b)Y_0}{k - rb}$$

where  $Y$  stands for income and  $g=rb$ , or as<sup>2</sup>

<sup>2</sup> There is an implicit assumption that  $g \geq 0$  and, hence,  $rb \geq 0$ . Negative values of  $g$ , the expected rate of growth of dividends, are possible, but they contradict the assumption either of a constant rate of growth or of no outside financing. For example, consider a  $g < 0$ . This means that  $r < 0$ , since  $0 \leq b < 1$ . However,  $r < 0$  implies a constant rate of deficit.  $(1-b)$  times a deficit is a negative expected dividend, or forced capital subscription, which contradicts the outside financing assumption. To allow outside financing only of this sort does not enhance the realism of the model. A heuristic resolution of the problem might be that the infinite-horizon model is an approximation, that the expectation of constant  $r$  and  $b$  is approximate, and that temporary negative  $r$  (and therefore  $g$ ) for a going concern is possible.

$$(1.4'') \quad P_0 = \frac{(1-b)rA_0}{k-rb}$$

where  $A_0$  stands for total assets.

### *The "Optimum" Retention Rate*

The model described in equations 1.4 and 1.4' suggested ways in which the question of the optimum dividend rate (or optimum retention rate) could be approached. Assume  $r$  is fixed, for clearly it is not independent of  $b$ . If the partial derivative of  $P$  with respect to  $b$  is set at zero, the price of the stock will be at a maximum if the second derivative is negative at this value. Taking the first partial derivative, it can be seen that  $\partial P/\partial b = 0$  when  $r$ , the internal rate of return on assets, equals  $k$ , the market rate of discount. Upon taking the second derivative, however, it is seen that  $\partial P/\partial b > 0$  only where  $r > k$ , and  $\partial B/\partial b < 0$  only where  $r < k$ . Stated differently, where the first-order condition,  $\partial P/\partial b = 0$ , is satisfied, the second-order condition cannot be because the second and higher derivatives disappear. Therefore, the conclusion is reached that if  $r$  is greater (less) than  $k$ , the price of the stock rises (falls) with a rise in retained earnings.<sup>3</sup>

Further implications can be derived from this unsuccessful attempt to find the optimum retention rate. Substituting  $k$  for  $r$ ,<sup>4</sup> its value when  $\partial P/\partial b = 0$ , in the denominator of equation 1.4' yields

$$(1.5) \quad P = \frac{(1-b)Y}{k-kb} = \frac{Y}{k}.$$

Thus, in a single-equation valuation model such as 1.4'', the capitalized value of a corporation's dividend stream equals the capitalized value of its earnings stream if the corporation continues to invest until the rate of return on assets equals the market rate of discount.

This should not be considered a surprising result, considering the fixed definitional relationship between earnings and dividends. That an earnings model and a dividend model may lead to identical valuation of share prices has been demonstrated by Gordon [3, Ch. 5], Lintner [7, p. 256], and Miller and Modigliani [5]<sup>5</sup> under various conditions and

<sup>3</sup> Gordon proceeded in this manner and went on to state, "A moment's reflection on the conclusion just reached with respect to the variation in share price with  $b$  reveals that a corporation should retain all of its income or liquidate depending on whether  $r \leq k$ " [3, p. 48]. He then speculated that this curious result probably stemmed from the assumption of independence of  $r$  and  $b$ , but with only one equation he was unable to follow the implications of this insight.

<sup>4</sup> Having developed present value valuation, subscripts from this point on refer to different values rather than different time periods.

<sup>5</sup> This study goes on to show that the valuation of shares will be identical not only under a dividend model and an earnings model, but also under a discounted cash-flow approach and the current earnings plus future investment-opportunities approach.

with different purposes in mind. What is significant is that  $P$  in equation 1.5 does not depend upon  $b$ , nor in fact does it depend upon  $r$  or  $k$ . If  $r$  is substituted for  $k$  in equation 1.4'', then at the point where  $\partial P/\partial b = 0$ ,

$$(1.5') \quad P = \frac{(1-b)rA_0}{r-rb} = A_0,$$

or the price of the stock equals the book value of the corporation (since the assumption of no debt was made). With  $r$  held constant and greater than  $k$ , the price of the stock commands a premium over book value and rises as  $b$  increases. If  $k$  is greater than a constant  $r$ , the price of the stock is less than book value and falls with a rise in  $b$ . While intuitively reasonable, the applicability of these results is limited because the manner in which they could be reached is unspecified. That is, if the retention rate is viewed as the firm's decision variable, it is reasonable to suppose that the value of the firm's stock would rise with an increase in its retention rate if internal opportunities remain greater than the shareholders' capitalization rate. On the other hand, the attempt of corporate management to proceed in its retention policy to the point where  $r=k$  yields the unacceptable conclusion of equation 1.5'. The difficulty lies in not spelling out how  $r$  and  $k$  might, in fact, change with changes in  $b$ . Plainly, shareholders' discount rate and the rate of return on assets are not invariant with respect to changes in dividends and reinvestment of earnings. Instead of holding  $r$  and  $k$  fixed, and then tracing the effects of varying  $b$  on  $P$ , a more useful way of working with equation 1.4'' may be to allow all four variables to change. As a first step, we continue to hold  $k$  constant and map the  $r, b$ , and  $P$  relationship.

If 1.4'' is written as

$$(1.4''') \quad r = \frac{Pk}{b(P-A) + A},$$

iso-price lines can be traced on a graph whose axes are  $r$  and  $b$ .

$P_2$  is higher than  $P_1$  and both are greater than the corporation's book value.  $P_{-1}$  is higher than  $P_{-2}$  and both are less than book value. Figure 1 illustrates that for a given  $r$ , say  $r_0 > k$ , the price of the stock rises as  $b$  increases from  $b_1$  to  $b_2$ . If  $r_0$  were less than  $k$ , the price would fall with increases in  $b$ . Moreover, for a given  $b$ , the price of the stock rises as  $r$  increases.

Figure 1 highlights the fact that all the iso-price lines approach  $k$  as  $b$  approaches 1.<sup>6</sup> It therefore follows that a given absolute change in  $r$

<sup>6</sup> Since  $k > rb$  in general, but for  $P > A$ ,  $k < r$ , it is clear that  $b$  can only approach 1 for  $k < r$ . The integrability constraint would be violated if this were not the case.

will lead to a larger price change, the higher the level of  $b$ . This can be seen analytically by considering  $\partial P / \partial r = (1-b)kA / (k-rb)^2$  in the limiting cases where  $b=0$  and  $b$  is close to 1. Phrased differently, stocks that have a high retention rate (low dividend payout rate) will fluctuate more in price for given changes in  $r$  than securities with a low retention rate. A similar conclusion was reached by Malkiel [8].

A shift in  $k$ , the market rate of discount, will change the location of the iso-price lines. For example, if  $k$  should fall as a result of a general decline in interest rates, and if  $r$  and  $b$  remain constant, some iso-price lines that formerly had positive slopes will now acquire negative slopes. Thus, if  $k$  changes, the shares of a corporation may sell at a premium over book value (or any other specified price) at one time and at a discount from this price at another, even though the corporation continues to earn the same internal rate of return and follows the same dividend policy. More importantly, a corporation whose present price line shifted from negative to positive slope, say, would find that the consequence of an increase in the retention rate was a fall in share price, whereas formerly a rise would have resulted.

The difficulty with Figure 1 and its supporting equation as they now

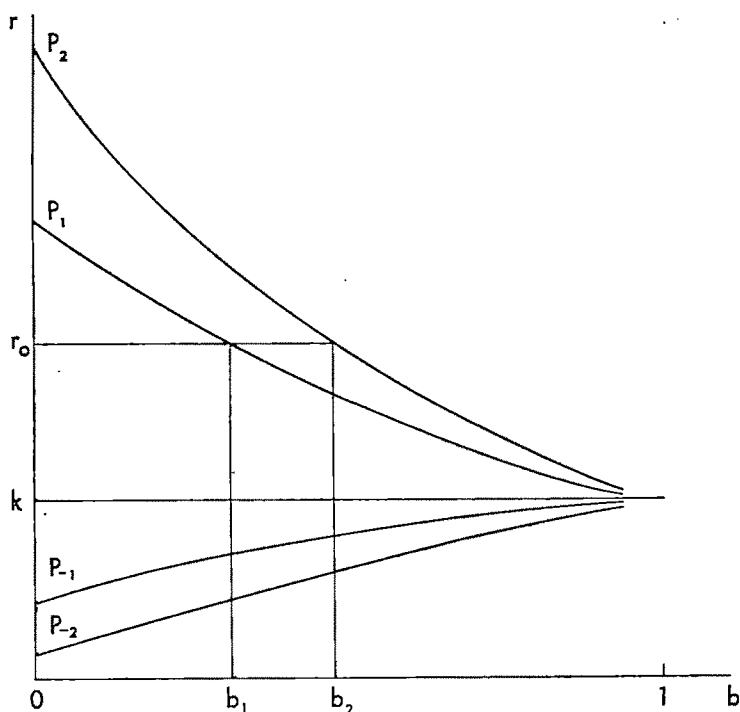

FIGURE 1

stand is that no provision is made for  $k$  to vary and no bounds are placed on the interaction of  $r$  and  $b$  within the firm; hence,  $P$  is indeterminate. Such also is the type of problem faced in the capital-budgeting decision. In that context,  $P$  is usually assumed to be given and the question is asked: "What rate of return must be earned by the corporation if  $P$  is to remain at its assumed level?" The more relevant question centers on the behavior of  $P$  under various combinations of  $r$  and  $b$ <sup>7</sup> and, more specifically, on the capital budget that will make  $P$  a maximum. Without internal constraints on the firm or specification of how  $k$  depends on  $r$  and  $b$ , the problem cannot be resolved. Our next step is to specify  $k$ .

### *Specifying $k$*

Except for the constraint that  $k$ , the rate of discount, be greater than  $rb$ , the rate of growth of dividends,  $k$  has not been specified. If for no other reason than to avoid the growth-stock paradox,  $k$  should be related to the firm's expected growth. More importantly from a practical point of view, as indicated above, the suggestion that  $k$  is a constant rather than a function leads to unacceptable capital-budgeting-decision results.

As a manageable form for such a function we propose:

$$(1.6) \quad k = \alpha + \psi rb$$

where  $\alpha$  is the market interest rate on growthless shares<sup>8</sup> and  $\psi$  is a risk class specification.<sup>9</sup>  $\psi$  is a constant which can assume values between 0 and 1.<sup>10</sup>

At this stage of the analysis there is some parallel between Modigliani and Miller's risk-class concept and our own. That is, a  $\psi$  class would be made up of corporations whose growth rates ( $rb$ 's) would be discounted in like fashion because in other respects they were similar. Since  $\psi$  has not yet been specified (except by its range of possible values) and since debt has not yet been introduced into the capital structure of the firm, principal sources of expected instability in the firm may in-

<sup>7</sup> One method of handling this problem was suggested by Cheng and Shelton [1].

<sup>8</sup> Under the assumption of an infinite stream of returns, yield to maturity equals current yield, a characteristic, for example, of consols. Because the dividend stream in this valuation model is discounted over an infinite horizon,  $\alpha$ , the market interest rate, is equivalent to a consol yield and might be approximated by the current yield on a growthless long-term security.

<sup>9</sup> Other forms for a risk-discount function are of course possible.

<sup>10</sup> This condition gives the limits of  $\psi$  when  $\alpha = 0$ . Since in the real world  $\alpha > 0$ , equation 1.3 could still be integrated for some  $\psi < 0$ . Of course, if  $\psi < 0$ , this would imply that future dividends are worth more than current dividends. Furthermore, although  $rb < 0$  gives rise to the logical problems of negative growth, as discussed in footnote 2, it is clear that with  $0 \leq \psi \leq 1$ , integrability conditions are not violated:  $k - rb > 0$ .

clude previous instability of growth due to industry competition, demand elasticity, vulnerability to technological change, and the like. The greater the degree to which these forces were operative in the past, the more likely, *ceteris paribus*, they are to be operative in the future. Put slightly differently, when such forces have been significant, there is a greater presumption that they will continue to be so. For example, a high expected growth rate for a firm is more likely to attract competition if barriers to entry have been low, and this possibility creates uncertainty with respect to the mean-value expectation of growth. Since Modigliani and Miller were interested primarily in the effect of leverage on the discount rate, they removed dividend payout from center stage by assuming it already decided in the stockholders' best interests [11, p. 266]. They then defined the discount rate as a linear function of leverage alone, suppressing the growth rate-discount relationship. We prefer to start at a more fundamental level and define  $k$  as a linear function of growth even before introducing the leverage problem. At one extreme a  $\psi$  value of 0 implies the uniform rate of discount we have already discussed. If  $\psi = 1$ , the rate of discount rises one-for-one with the expected rate of growth, and stockholders will pay no more for the high growth company than for the zero growth firm. As an example of the latter possibility, if the only source of growth was expected inflation of dividend dollars and shareholders insisted on evaluating their prospects in real terms,  $\psi$  would equal 1.

Substituting equation 1.6 into 1.4<sup>9</sup> yields

$$(1.7) \quad P = \frac{(1-b)rA}{\alpha + \psi rb - rb}.$$

The first partial derivative of  $P$  with respect to  $b$  equals 0 when  $r = \alpha / (1-\psi)$ , and once again the second derivative will be positive or negative depending upon whether  $r(1-\psi) \gtrless \alpha$ .<sup>11</sup> A graph of this expression would be similar to that of Figure 1 above with the difference that  $k$  would be replaced by  $\alpha / (1-\psi)$ . Similarly, substituting the value  $\alpha$  for  $r(1-\psi)$  in equation 1.7 yields

$$(1.8) \quad P = \frac{rA}{\alpha}.$$

Once again, with  $r$  a fixed number, there is a point ( $\partial P / \partial b = 0$ ) at which  $P$  is independent of  $b$ , or the dividend model produces the same price as an earnings model. More importantly, at this point the risk class falls out. This result makes intuitive good sense and justifies the form given the discount function for, if  $r$  is fixed and  $b$  has been set by dif-

<sup>11</sup> Again, under the assumption that  $dr/db = 0$  or that  $r$  is fixed.

ferentiation at the point at which it does not influence share price, then growth ( $r$ ) does not affect capitalization.

Equation 1.8 can also be rewritten as

$$(1.8') \quad r = \frac{\alpha P}{A}.$$

In this form the equation focuses attention on the rate of return that a corporation must earn on its assets if its shares are to maintain their existing price. Equation 1.8' also serves to put to rest the alleged "IBM paradox": Should not a corporation that sells at 50 times earnings invest in any asset yielding over 2 per cent? If  $\alpha$ , the market rate of interest on securities with no growth, equals 4 per cent, if the security sells at five times its book value, and if the retention rate is that which makes  $\partial P/\partial b = 0$ , then the required rate of return necessary to keep the price of the stock at its present level is 20 per cent, not any value greater than 2 per cent. As indicated earlier, however, equation 1.8' does not provide an answer to what rate must be earned to maximize  $P$ , let alone to what happens to  $r$  when  $b$  is determined.

A further interesting result can be obtained from equation 1.8'. When the firm's capital budget is set at  $\partial P/\partial b = 0$ , then  $\alpha = r(1 - \psi)$ , or

$$(1.9) \quad \psi = 1 - \frac{\alpha}{r} = 1 - \frac{\alpha A}{P}.$$

Since, under the assumption of an infinite shareholder time horizon,  $\alpha$  can be replaced by the current earnings yield, the  $\psi$  class of a security when  $\partial P/\partial b = 0$  will be given by:

$$(1.10) \quad \psi = \frac{P - A}{P}.$$

Note that  $\psi = 0$  when the price of the stock equals its book value.<sup>12</sup> As the price rises from book value,  $\psi$  increases. Equation 1.10, or some variant, has a long history of use among practitioners of security analysis and portfolio management. In the language of "The Street," risk rises when the security commands a substantial premium over book value. Indeed, one portfolio manager has gone so far as to state that when securities sell for more than six times book value (a  $\psi$  class of .83 under our assumptions), they no longer belong in a prudent man's portfolio [4].

<sup>12</sup> Since  $0 \leq \psi \leq 1$ ,  $P \geq A$ , which might seem to be an unnecessarily strong result. On the other hand, if  $P < A$  and the firm is doing the best it can, then it probably should liquidate. This conclusion is equivalent to Gordon's and follows from essentially the same situation as his case of  $r < k$ .

*Introduction of Debt into the Capital Structure*

Debt can be formally introduced into the single-equation valuation model as follows:

Let the change in assets in a continuous model be represented by the change in equity plus the change in liabilities:

$$(1.11) \quad dA = dE + dL.$$

The change in equity equals retained earnings:

$$(1.12) \quad dE = A r_L b,$$

where  $r_L$  is now the levered internal rate of return, or rate of return on assets less interest expenses imposed by the existence of debt. Let the change in debt be represented by  $dL = L\mu$  where  $\mu$  is some constant. If the ratio of debt to equity is assumed to remain constant,<sup>13</sup> then

$$\frac{dE}{dL} = \frac{E}{L} = \frac{A r_L b}{L\mu}.$$

Therefore,

$$\mu = \frac{A r_L b}{E}.$$

If  $z = L/A$ ,

$$(1.13) \quad \mu = \frac{A r_L b}{A - L} = \frac{A r_L b}{A - Az} = \frac{r_L b}{1 - z}.$$

Substituting 1.12 and 1.13 into 1.11:

$$\begin{aligned} dA &= A r_L b + \frac{L(r_L b)}{(1 - z)} \\ &= r_L b \left[ A + \frac{Az}{1 - z} \right] = \frac{A r_L b}{1 - z}, \end{aligned}$$

or

$$(1.14) \quad \frac{dA}{A} = \frac{r_L b}{1 - z}.$$

The percentage change in assets is precisely the term we have called  $g$  in equation 1.4, by virtue of equation 1.1' and the assumption that  $D = (1 - b)rA$ . Substitution of equation 1.14 into 1.4 yields a valuation model for a corporation with a fixed percentage of debt in its capital

<sup>13</sup> For an empirical justification of this assumption, see Lindsay and Sametz [6, Chs. 18 and 19], and Miller [9].

structure ( $k$ , however, is unspecified at this point):

$$(1.15) \quad P = \frac{(1-b)r_L A}{k - \frac{(r_L b)}{(1-z)}}.$$

Equation 1.15 suggests the following question: What is the optimum ratio of debt to assets for a corporation, abstracting from taxes? The first derivative of  $P$  with respect to  $z$  shows that so long as  $k(1-z) > r_L b$ , the price of the security will rise with a rise in the ratio of debt to total assets, and as  $k(1-z)$  approaches  $r_L b$ , the change in price associated with a change in debt approaches infinity. The assumption that  $k$  is independent of  $z$ , however, is not very useful. Indeed, one of the classic controversies in finance centers on the behavior of  $k$  over various ranges of  $z$ . Modigliani and Miller's famous proposition—in terms of equation 1.15—is, of course, that  $k$  rises linearly with  $z$  so that the average yield of the sum of debt plus equity remains constant. The more conventional position is that  $k$  does not change for low levels of  $z$ ; however, as  $z$  continues to rise,  $k$  rises faster than  $r_L b/(1-z)$ . Under this conventional view, the price of a stock, therefore, first rises and then falls as progressively larger amounts of debt are introduced into the capital structure.

An alternative behavioral assumption allows  $k$  to change with changes in the debt-asset ratio. Such a specification may be given by

$$(1.16) \quad k = \alpha + \psi r_L b + \phi z$$

where  $\phi$  is same constant greater than zero. Substituting equation 1.16 into 1.15 gives a stock-valuation model that incorporates debt:

$$(1.17) \quad P = \frac{(1-b)r_L A}{\alpha + \psi r_L b + \phi z - \frac{(r_L b)}{(1-z)}}.$$

For corporations that have no debt, it will be recalled that  $\partial P/\partial b = 0$  when  $r = \alpha/(1-\psi)$ , where the absence of a subscript means that  $r$  is unlevered. The change in  $P$  with respect to a change in  $b$  for corporations with debt equals zero when

$$(1.18) \quad r_L = \frac{(1-z)(\alpha + \phi z)}{1 - \psi + \psi z}.$$

If  $z=0$ , equation 1.18 is identical to the case of a corporation with no debt;  $r_L$  is the rate of return after interest that a corporation must earn on assets if the price of the stock is to remain constant with respect to a change in retention rates.

The treatment of debt, however, suffers from being essentially arbitrary. Moreover, the implication of debt in the capital structure has not been carried through to the stream of dividends. Even if these difficulties are accounted for, the retention rate which maximizes  $P$  is indeterminate.

## II. A General Model

In Section I we developed a stock-valuation model that specified  $k$  and incorporated debt as part of the capital structure. While useful insights are obtained from this model, its usefulness is limited. The principal kinds of questions that can be answered within the model's framework are of the sort: given a  $P$  and a  $z$ , what is the  $b$  which will just maintain the present  $P$ ? Of greater interest is a model which allows more logical "degrees of freedom." In this section we develop a set of two equations in  $r$  and  $P$ , one the stock-valuation equation, the other an investment-opportunities schedule. Simultaneous solution of these for some  $b$  yields  $r$  and  $P$ .

### *The LC Schedule*

The investment-opportunities schedule facing a corporation at a point in time can, with reliance upon traditional economic thinking on the subject, be taken as a function linking inversely the expected rate of return on total assets and size of capital budget.<sup>14</sup>

The development of a stock-valuation model invoked shareholders' expectations of  $r$  and  $b$ ; the present section deals with management's (expected) constraints on  $r$  and  $b$ . Apart from equilibrium requirements, and undoubtedly in the everyday world, the possibility exists that shareholder and management point estimates of  $r$  and  $b$  will diverge. It, therefore, becomes useful to introduce new notation:  $r_I$  and  $b_I$  to stand for investor (shareholder) expectations of rate of return and retention rate, and  $r_C$  and  $b_C$  to be expectations of the same variables held by the corporation (management).

With this convention, and recalling that the capital budget is defined identically by the corporation's earnings-retention rate,<sup>15</sup> a reasonable form for the investment opportunity schedule would be:

$$(2.1) \quad LC(r_C, b_C) = \gamma_0 \geq \frac{r_C}{1 + \gamma_1 b_C},$$

<sup>14</sup> The more common statement links the return on the marginal investment to the marginal investment. It is clear that our formulation is consistent, for if  $r$ , which is the average return on total assets, declines, then so does  $r'$ , the marginal return. The reason for our formulation rests on the fact that (from the stock-valuation equation)  $r$  rather than  $r'$  is the focus of capital-budget decisions designed to maximize share price.

<sup>15</sup> Depreciation is not considered a source of funds because we are interested only in net investment.

where  $\gamma_0(\geq 0)$  is the average rate of return expected when retained earnings are zero, and  $\gamma_1(<0)$  reflects the declining return associated with movement down an opportunities schedule as  $b$  increases. To show the nature of the functional relationship of  $r_c$  and  $b_c$ , inequality 2.1 may be written as

$$(2.2) \quad r_c \leq \gamma_0 + \gamma_0\gamma_1 b_c.$$

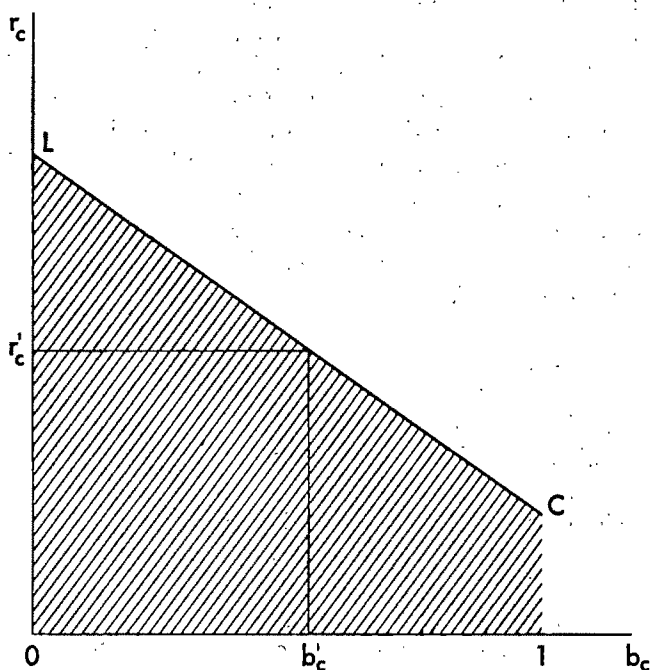

FIGURE 2

The shaded area in Figure 2 is feasible; for the efficient firm, 2.2 may be written as an equality:

$$(2.3) \quad r_c = \gamma_0 + \gamma_0\gamma_1 b_c.$$

It should be emphasized that this function is a set of equilibrium points, not a demand curve. For the corporation with no debt, no external financing, and no liquidating dividends, the domain of  $LC$  is from  $b=0$  to  $b=1$ . The choice of  $b_c$  (and, hence, of  $r_c$ ) remains indeterminate for the corporation until it is known which retention rate will, in fact, maximize share price.

### *The Complete Model*

Recall Figure 1 in which, from equation 1.4'',  $r$  was expressed as a

unique function of  $b$ , given  $P$  and  $k$ . In terms of this section:

$$(1.4'') \quad P = \frac{(1 - b_I)r_I A}{k - r_I b_I},$$

or

$$(1.4''') \quad r_I = \frac{Pk}{b_I(P - A) + A} = \frac{P\alpha}{b_I[P(1 - \psi) - A] + A}.$$

As with equation 2.3, it is clear that the valuation model is incomplete. To state the matter differently, we can fix  $P$  and  $b_I$  and find  $r_I$ , but how do we arrive at a  $P$ , much less at a maximum  $P$ ?

The answer lies in the simultaneous solution of equations 2.3 and 1.7. This can most easily be seen by tracing the steps from choice of  $b$  (the corporation's decision variable) to final determination of  $P$ . As a first step, it is necessary to impose the equilibrium conditions that

$$(2.4) \quad r_C = r_I$$

$$(2.5) \quad b_C = b_I$$

in order that there be no divergence in expectations. That is, shareholders accept the firm's retention-rate decision and agree with its assessment of the consequences on rate of return (whether or not they like it).

Then it can be seen that, with exogenous  $A$ ,  $\alpha$ , and  $\psi$ , equation 1.7 expresses share price as a function of  $r$  and  $b$  and that equation 2.3 is also a function in the same two variables. Once the firm chooses its retention rate,  $b$ , then  $r$  is determined from the latter function. However, substitution of the values for these variables in the stock-valuation equation 1.7 produces a unique share price.

The problem of suboptimum price arises in an equilibrium context because, although shareholders may agree with the corporation's assessment of its retention policy, they would be better off with some other policy that produced some other return, which might be either higher or lower. Solution of maximum price is somewhat more easily described with equations 1.4''' and 2.3. The maximum price then is given by the familiar tangency condition:

$$(2.6) \quad \left( \frac{\partial r}{\partial b} \right)_{\text{eq. 1.4'''}} = \left( \frac{\partial r}{\partial b} \right)_{\text{eq. 2.3}}.$$

Under the conditions assumed, only one  $P$ , a unique maximum, satisfies the condition that these two slopes be equal.

$$\left( \frac{\partial r}{\partial b} \right)_{\text{eq. 2.3}} = \gamma_0 \gamma_1 < 0$$

and

$$\left(\frac{\partial r}{\partial b}\right)_{\text{eq. 1.4}'''} < 0 \quad \text{for } P(1 - \psi) > A.$$

Furthermore, because the second partial derivative of  $r$  with respect to  $b$  is zero for the right-hand side and positive for the left-hand side of 2.6, for  $P(1 - \psi) > A$ ,<sup>16</sup> the appropriate convexity of the iso-price lines within the allowable range of the  $rb$  plane is satisfied.<sup>17</sup> Figure 3 de-

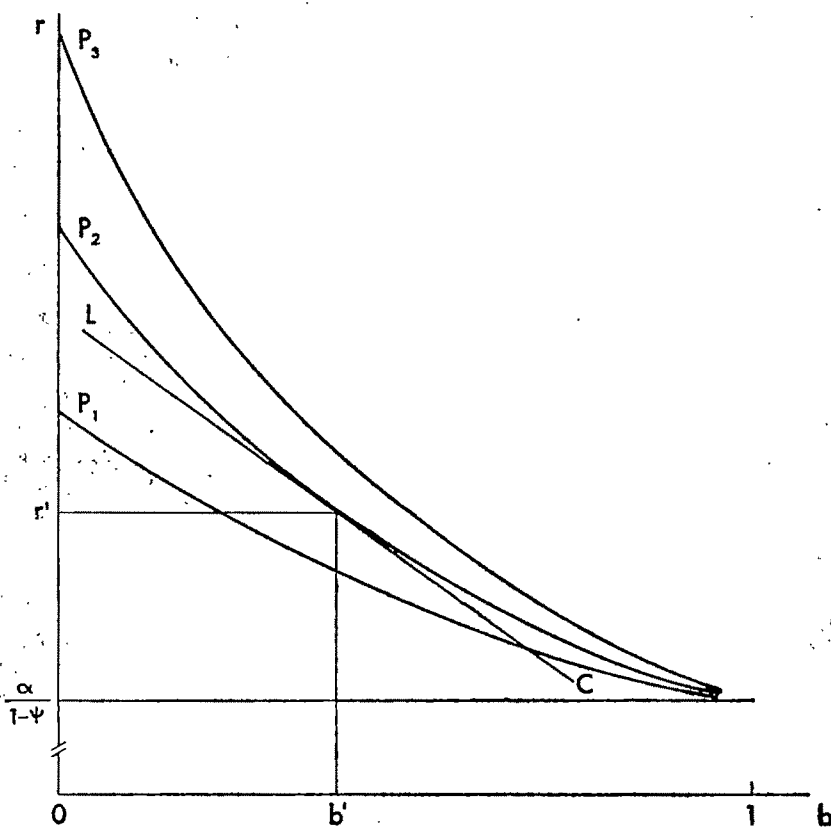

FIGURE 3

<sup>16</sup> It may be asked why this statement of a general model was not handled by the more familiar technique of Lagrange multipliers: maximize equation 1.4 subject to equation 2.1. While such a method yields the same results plus valid economic insights into the nature of the valuation *cum* capital budget problem, a comment is in order. In general  $b_0 \neq b_1$  and  $r_0 \neq r_1$ . Satisfaction of conditions 2.4 and 2.5 is necessary to secure simultaneous firm and market equilibrium *at any price*. Although the consequences of not meeting these conditions are best dealt with in dynamic models (and will be so handled in a forthcoming paper), we prefer not to suppress them this early in the game.

<sup>17</sup> We have drawn the  $LC$  function *above*  $\alpha/(1 - \psi)$ , indicating the firm has opportunity for

scribes the solution of the stock-maximization problem, where  $b'$  is the solution value of the corporation's decision variable.

The firm faces only one investment-opportunities schedule, downward-sloping, at a point in time, but an entire family of share prices. Without condition 2.6 an infinite number of prices are possible since the  $LC$  function intersects infinitely many iso-price lines. Condition 2.6 allows us to find a maximum price, i.e., where the slope of the  $LC$  function equals the slope of an iso-price line.

Maximizing profits, that is, carrying on investment projects until  $r = \alpha/(1-\psi)$ , is an inadequate criterion for either capital budgeting or dividend payout policy. In the case of Figure 3, investment to the point where  $r = \alpha/(1-\psi)$  (or equivalently until  $r = k$ ) would clearly not be optimal, for once the point of tangency with an iso-price line is passed, movement down the  $LC$  function toward  $b = 1$  produces lower and lower share prices as (implicitly) less-profitable projects are undertaken. Such a course would only be another example of the alleged IBM paradox: Investment to the point where  $r = \alpha/(1-\psi)$  (or  $r = k$ ) represents the undertaking of projects whose returns are not regarded by the market as valuable as using the funds to pay greater dividends.

This conclusion that firms should not in general invest until  $r = \alpha/(1-\psi)$  is admittedly at variance with traditional statements on the subject. Such statements have assumed either a single equation which took  $P$  as given or an infinitely elastic investment-opportunities schedule. Positing a downward-sloping investment-opportunities schedule and a separate valuation equation leads to the results described above.

Figure 3 and the supporting equations also illustrate the fallacy of the proposition that a firm should retain all earnings or distribute all earnings depending upon whether  $r \geq \alpha/(1-\psi)$ . The idea that such a policy could be relevant arises only because the requirements of internal (rate of return) and external (share price) equilibrium are not dealt

---

an average internal return at least equal to the absolute required yield in the market adjusted for risk. For the firm whose  $LC$  function is below  $\alpha/(1-\psi)$ , the iso-price lines are concave downward, indicating that the best the firm can do is distribute all earnings; retaining and re-investing serves to lower  $P$ . As in Gordon's model, however,  $b$  can only approach 1. For  $r > \alpha/(1-\psi)$ , if  $b = 1$  the integrability constraint,  $r < \alpha/b(1-\psi)$ , is violated. The economic sense of this case—where the tangency is at or beyond the point where  $b = 1$ —is that a switch to external financing is called for. For  $r < \alpha/(1-\psi)$ , any  $b > 0$  lowers  $P$ . Hence the case of  $b = 1$  is not meaningful. Satisfaction of the second-order condition is guaranteed by the choice of a downward-sloping linear  $LC$  function. It therefore may be argued that our specification of the investment-opportunities schedule is fortuitous. On the other hand, other specifications would produce the same results, and the one chosen is consistent with economic tradition. It is interesting to note that the condition  $P(1-\psi) > A$  which is necessary for negative first derivative and positive second derivative is at variance with the results of equation 1.9 and 1.10 above, in which  $P(1-\psi) = A$  for  $\partial P/\partial b = 0$ . The reason for this difference is, of course, that the earlier result ignored the  $r, b$  relationship by considering  $r$  to be fixed.

with simultaneously. For the growing firm ( $P > A$ ), equilibrium at a maximum  $P$  is obtained only with an  $r > \alpha/(1-\psi)$  (i.e.,  $r > k$ ), which could require a  $b$  anywhere between 0 and 1. As discussed in footnote 17, for  $r < \alpha/(1-\psi)$ , the maximum obtainable  $P$  is at  $b=0$ .

This analysis also indicates the limitations of two other "rules of thumb" that allegedly characterize some corporate actions: adopting only those projects that yield more than a given rate of return and paying out a fixed percentage of earnings in dividends. If a corporation rejects all projects that yield less than an arbitrary set  $r_0$ , a dividend payment is dictated which is likely to be suboptimal with respect to share prices. Similarly, if a corporation adopts a fixed payout (retention) policy, the rate of return that will be earned may not maximize share prices.

A variety of possible situations are manageable within the comparative statics framework of this model. Consider first the effect of an upward shift in  $LC$ , the investment-opportunities schedule. The result is an increase in  $b$  and  $P$ , and possibly in  $r$ .

Consider now the selection of a retention rate higher than  $b'$ . Equilibrium for shareholders is possible now only at a lower  $P$  because the exploitation of too many internal opportunities lowers the average rate of return. Similarly, too low a retention rate will not maximize  $P$  because dividends are not valued as highly as some margin of the remaining internal opportunities. Securing equilibrium  $r$  and  $b$  together with a maximum  $P$  requires the firm to find a unique retention rate and its associated unique rate of return.

Consider finally the effect of a change in  $k$ . If, for example,  $k$  should rise because of a change in the demand for and supply of loanable funds (equivalently, if  $\alpha$  should rise), the iso-price lines will shift so that any given  $r$  and  $b$  will be associated with lower iso-price lines. With an unchanged  $LC$  schedule, the equilibrium  $P$  will fall. Moreover, the slopes of the iso-price lines will change for given rates of return. A new price line will now be tangent to the  $LC$  function and only by chance will the point of tangency be the same as where it was before the change in  $k$  occurred. The implication of this is that no single capital budget will be optimal under diverse external market circumstances.

### III. *Implications for Research*

In the previous section we defined a static equilibrium stock valuation-capital budgeting model. We demonstrated how  $r$  and  $b$  must vary if the price of a share is to be optimized under the assumption of a given  $k$  function and investment-opportunities schedule. We demonstrated the consequence of a shift in either the  $LC$  (investment opportunities) schedule, or  $k$ , as well as the consequences of a corporation's

choosing an  $r$  or  $b$  other than the one dictated by the tangency of the  $LC$  schedules and an iso-price line.

If the concept of the  $\psi$  class is introduced into the  $k$  function, the essential features of our equilibrium model are not altered. While the location and slope of the particular iso-price lines will change, the price of the security will still be optimized at the point of tangency between the  $LC$  function and the iso-price line.

The model assumed no ranking problems for investment projects: because  $r$  is the average return per year on total assets expected by firm and investor and is expected to be a constant, the related problem of finding the marginal profitability of projects having different time streams of returns is suppressed.

Risk was not introduced into the  $LC$  function because, arguing heuristically, the risk of the investor's discount function ( $\psi$  class) is the relevant consideration for firms trying to maximize  $P$ . Put another way, if firm and investors have the same mean-value forecast of  $r$ , the risk factor which influences  $P$  is that of the investors. Since the model presented in this paper is an equilibrium model, it cannot handle problems in disappointed expectations or consider measured variability as synonymous with risk. In an adjustment model,  $\psi$  might best be specified as a function of observed variance around  $r$ .

The introduction of debt as a variable, however, is more complicated. In this paper it was handled in an arbitrary manner and not treated as a corporate-decision variable. If debt is treated as a variable, another equation, linking debt to the dividend payout, is required. It also may be useful to consider debt in a dynamic context. In an adjustment model there will be an investor  $b$ -expectation function such as:  $b_t^* = b(b_{t-1}, b_{t-2}, \dots)$ . A decline in  $b^*$  will tend, *ceteris paribus*, to lower  $P$ . The question then arises: given an investment-opportunities schedule with tangency position at  $b > b^*$ , should the corporation borrow or reduce dividend payout? Quite possibly the former. Put another way, if investors do not discount increases in leverage too heavily (i.e., if  $\phi$  in equation 1.17 is not too large) and the opportunities schedule dictates asset growth, then maximum  $P$  suggests both borrowing and paying a  $(1 - b^*)$  dividend rate.

## THE PRICE OF U.S. EXPORTS AND THE MIX OF U.S. DIRECT AND INDIRECT TAXES

By ROBERT Z. ALIBER AND HERBERT STEIN\*

It is sometimes said that U.S. products could be made more competitive in foreign markets if the United States relied less on direct taxes and more on indirect taxes.<sup>1</sup> The reason is that prevailing practice and GATT rules permit indirect taxes, but not direct taxes, to be rebated at the border. This paper explains how a change in the mix of U.S. taxes might improve the international competitiveness of U.S. goods, and gives a rough indication of the likely magnitude of the improvement in different circumstances.

In 1961, the components of \$1.00 of U.S. Gross National Product were of the relative magnitudes shown in column 1 of Table 1.

If (a) the corporate profits tax is repealed; (b) a new indirect tax of equal yield is imposed; (c) everything else—that is, wages, interest and other costs, and other indirect taxes, and *corporate profits after tax*—remains the same; (d) the new indirect tax is rebated on exports; (e) the components of the price of \$1.00 of exports, before the tax change, are the same as the components of \$1.00 of GNP; then: (a) the U.S. price level will remain unchanged<sup>2</sup> (column 2), and (b) the price of U.S. exports will decline by 4.4 per cent (column 3).

It is unlikely, however, that the components of the price of \$1.00 of exports are the same as the components of the price of \$1.00 of GNP.

<sup>1</sup>This issue was one of several recently examined in the United Kingdom by Gordon Richardson, Henry Benson, and Sir Donald MacDougall. See *Report of the Committee on Turnover Taxation*, Her Majesty's Stationary Office. Cmnd. 2300, London, 1964, esp. pp. 75-77.

<sup>2</sup>The "U.S. price level" has three different meanings: (a) the price level of goods and services, domestic and imported, sold in the United States; (b) the price level of domestically produced goods and services sold in the United States; (c) the price level of U.S. output sold in the United States and abroad.

What happens to these three price levels in the conditions assumed here depends on the relative size of exports and of imports. Price level (a) will rise, because tax is shifted from sales abroad to sales at home. Price level (c) will decline because tax is shifted from exports to imports. Price level (b) will remain unchanged if exports and imports are equal. For the United States, with exports and imports and the difference between them small as percentages of GNP, the differences among the changes in these different "price levels" will be close to zero.

	<hr/> \$1.000	<hr/> \$1.000	<hr/> \$ .956

It also is unlikely that "everything else" will remain the same if a new indirect tax is substituted for the corporate profits tax. The implications of these two points are considered in turn.

### *I. The Components of the Price of Exports and the Components of the Price of GNP*

The reason for doubting that corporate profits taxes are the same proportion of the value of exports as they are of the value of total GNP is that corporations probably do not produce the same proportion of U.S. exports as they do of total GNP. In 1961 the GNP attributed to production by incorporated business was \$250 billion. If the total value of exports were produced entirely by unincorporated business, the elimination of the corporate profits tax would not affect the prices of U.S. exports, on the assumptions made above. (The term "production of exports" refers to all stages, including extraction of raw materials, fabrication, transportation, and finance.) The imposition of the indirect tax would raise the domestic price of the kinds of goods that are exported, but the rebate of the tax on exports would leave export prices unchanged.

At the other extreme, if the total value of exports were produced exclusively by corporations, corporate profits taxes would be a much larger proportion of the value of exports than of total GNP. In 1960, corporate profits taxes were 8 per cent of the value of GNP *produced by corporations*. Thus, if all exports were produced by corporations, the amount of corporate profits taxes included in the value of the exports, and consequently the possible reduction in the price of exports as a result of eliminating the tax, might be 8 per cent.

It is unclear whether corporations produce a larger or smaller proportion of U.S. exports than they do of GNP. Unincorporated business accounts for most of agricultural production, and exports of agricultural products account for 20 per cent of U.S. exports. On the other

hand, government and some personal service industries that also are largely unincorporated account for a substantial portion of GNP and contribute little to the production of exports.

A helpful first approximation is that corporate profits taxes constitute about the same proportion of the value of exports as they do of GNP (4.4 per cent in 1961); the actual ratio of these taxes to exports is almost certain to fall within a range of from 3 per cent to 6 per cent. To facilitate the discussion, it is assumed that corporate profits taxes constitute 5 per cent of the value of exports.<sup>3</sup>

## *II. The Effects of the Change in the Tax Mix on the U.S. Price Level*

Thus far it has been assumed that "everything else" remains the same when the corporate profits tax is repealed and a new indirect tax of equal yield is imposed. The relevant issue is what happens to the U.S. price of GNP. The assumption that "everything else" remains unchanged is extreme; it lies at one end of a range of possibilities. If U.S. domestic prices do not rise as a result of the tax change, the price of U.S. exports will diminish by the amount of the rebate on exports that the change in the tax mix permits. The other possibilities generally have the effect of reducing the decline in U.S. export prices, and consequently the improvement in U.S. international competitiveness that might be expected from the change in the tax mix. At the other extreme, if U.S. domestic prices rise by the amount of the new indirect tax, the rebate of the tax will serve only to keep U.S. export prices constant and will not improve the competitiveness of U.S. exports.

The question of what happens to U.S. prices if the corporate profits tax is replaced by an indirect tax is usually considered as if it were identical with the question whether corporate taxes are "passed on in higher prices." It is argued that if corporate taxes are passed on, the elimination of this tax will reduce prices per unit of output by the amount of corporate profits taxes per unit of output. The imposition of an indirect tax of equal yield would then raise prices back to their initial level. On the other hand, if corporate taxes are not passed on in higher prices, the elimination of the corporate taxes will not reduce prices, but will raise corporate profits after tax. The imposition of the indirect tax then will cause a net increase in domestic prices.

This argument, however, does not answer the question of the effect of a change in the tax mix on export competitiveness. The general focus of most analyses of the incidence of the corporate tax—i.e.,

<sup>3</sup> This discussion assumes that, within the corporate sector, the rate of profit is the same on export sales as on domestic sales. To the extent that the rate of profit is lower on export sales than on domestic sales, the estimated reduction of export prices that would follow elimination of the corporate tax also is lower.

whether it is passed on in higher prices to others or borne by owners of corporate equities in lower incomes—is essentially on the effects on real profits or profit rates and of the *share* of profits in total income. Such analyses do not examine the impact of the corporate tax on the level of prices, the relevant factor for exports.<sup>4</sup> The “passing on” of corporate profits taxes is consistent with either changes in the price level or an unchanged price level, and so is the “absorption” of the corporate profits taxes.

Several possibilities are illustrated in Table 2. Column 1 presents a rounded-off version of the 1961 data as the initial situation.

TABLE 2—COMPONENTS OF PRICE PER \$1.00 OF OUTPUT

	Initial Situation	Pass-on Theory		Absorption Theory	
		Constant Prices	Higher Prices	Constant Prices	Higher Prices
Costs (mainly wages)	\$ .9000	\$ .9000	\$ .9474	\$ .8550	\$ .9000
Corporate profits after tax	.0500	.0500	.0526	.0950	.1000
Corporate profits tax	.0500	—	—	—	—
New indirect tax	—	.0500	.0526	.0500	.0526
U.S. Price	\$1.0000	\$1.0000	\$1.0526	\$1.0000	\$1.0526
Price of U.S. exports, after rebate of new indirect tax	\$1.0000	\$ .9500	\$1.0000	\$ .9500	\$1.0000

Column 2 reflects the initial assumption that a new tax is substituted for the corporate profits tax while everything else remains the same. U.S. prices remain constant, and export prices fall by 5 per cent. The impact of the elimination of the corporate profits tax has been passed on in the form of a reduction in prices, and the new indirect tax has been passed on as an addition to prices. (This also can be viewed as a case in which the corporate tax had been absorbed by profits and the indirect tax is now absorbed by profits.) Real corporate profits after tax remain unchanged.

Column 3 assumes that the initial effect of the shift in the tax structure is to raise prices. In some industries, for example, the amount of new indirect tax will exceed the amount of the reduction in corporate taxes, and their prices would tend to rise. While the reverse would be

<sup>4</sup>For example, the main test of the incidence of the corporate profits tax used by Kryzaniak and Musgrave in their recent study is the effect of the tax on the rate of return on corporate capital. See Marlan Kryzaniak and Richard A. Musgrave, *The Shifting of the Corporation Income Tax* (Baltimore 1963).

true in other industries, prices might not fall there, at least at once, because of downward rigidity, a rise in short-run marginal costs due to the indirect tax, and an effort to see whether the rise in after-tax profits can be made to stick. Thus there could be an initial increase of average prices and of corporate profits after tax if financial policy is permissive and permits an increase in the price level. Wages might then rise because of the rise in prices and in corporate profits after tax. The increase in wages would lead to higher prices in the noncorporate sector and absorb some of the initial increase in profits after tax in the corporate sector. Column 3 shows one possible point where this process might stop; at this point the elimination of the corporate profits tax has been completely passed on. *Real* corporate profits after tax are the same as in columns 1 and 2; the increase in corporate profits in money terms is proportional to the increase in the price level. So are "real taxes" and real "other costs." However, everything is at a higher price level, with the result that after the rebate of the new indirect tax, U.S. export prices are as high as before the change in the tax mix.

Column 4 assumes that corporate profits taxes have been absorbed in a reduction of corporate profits after tax and that the elimination of the tax will increase corporate profits after tax. If product prices are constant when the tax change is made and profits after tax rise, other costs, mainly wages, must fall. A shift from a corporate profits tax to a general indirect tax reduces the after-tax productivity of labor and raises the after-tax productivity of capital. Incorporated business will pay more for capital and less for labor than before the tax change.<sup>5</sup> If financial conditions are not permissive, so that the price level does not rise, the decline in the productivity of labor will result in higher unemployment until money-wage rates fall.

The result in column 5 also depends on a decline in the real productivity of labor as a result of the change in the tax mix. It differs from column 4 in that it is assumed that money-wage rates will not fall and that financial policy is permissive and permits an increase in the price level. In this case prices will rise enough to depress *real* wage rates to the level consistent with high employment. The price of U.S. exports will not decline.

It is conjectural which of these four results, or various intermediate possibilities, would follow the shift from the corporate profits tax to an indirect tax. The answer depends partly on the corporate response

<sup>5</sup> A roughly correct way of looking at this point is that before the tax change, if a business added \$1.00 to its labor cost, it added nothing to its taxes, while if it added \$1.00 to its equity capital cost, it added \$.50 to its taxes. After the tax change it adds approximately \$.05 to its taxes for each \$1.00 of additional cost of either kind.

to the change in the tax mix, partly on the response of labor to changes in prices, profits, and employment, and partly on the permissiveness of financial policy in response to changes in business costs.<sup>6</sup>

### III. *The Reaction in Foreign Countries to the Change in the U.S. Tax Mix*

That other countries have corporate taxes is relevant to this discussion for two reasons. First, it is usually said that the U.S. international competitive position is handicapped because direct taxes are

excessively high in the United States compared to the direct taxes in other countries. If this is the main point, it seems appropriate to "equalize" the U.S. corporate profits tax with those of other countries (whatever that means) rather than to eliminate the U.S. corporate tax. Second, even if the United States sought to obtain the maximum trade

<sup>\*</sup> It might also be noted that if foreigners buy \$16 billion of U.S. goods *produced by corporations*, they "pay" the corporate tax if the tax has been passed on. The tax burden on foreigners would decline perhaps by as much as \$300 million, if the corporate tax were repealed.

advantage from the elimination of the corporate tax, the possibility exists that other industrial countries would also eliminate or reduce their corporate tax.

Table 3 shows corporate tax revenues as a percentage of GNP in 1961 in the United States and in other large industrial countries.<sup>7</sup> While the U.S. effective corporate tax rate generally is higher than in most countries, the difference amounts to less than 2 percentage points of GNP.<sup>8</sup> If each country eliminated its corporate profits tax, and if the export prices of each country fell by the percentage that corporate taxes are of its GNP, then U.S. export prices would decline by no more than 2 per cent relative to export prices of major competitors of the United States.

Actually the ratio of corporate profits tax included in the value of exports to the value of exports is relevant rather than the ratio of corporate profits tax to GNP. These ratios may differ in other countries, as well as in the United States. The spread between the effective rate of corporate taxes on exports in the United States and in other countries may be smaller than is suggested by Table 3; it appears unlikely that it would be larger. Corporations probably contribute a larger proportion of the total exports of the Western European countries and Japan than they do of their GNP because agriculture provides a smaller percentage of their exports than of their GNP.

Moreover, if the tendency to "pass on" the elimination of the corporate profits tax is greater in other countries than in the United States, the decline in U.S. export prices relative to those abroad would be smaller, and conversely. If the elimination of the corporate tax were completely passed on in the United States, but absorbed in higher prices abroad, the U.S. export prices might decline by 5 per cent relative to those of other countries; in the reverse situation, U.S. export prices might rise relative to those of other countries by about the same amount.

<sup>7</sup> The 1961 data have been used because comparisons with other countries are not readily available for later years. It might be noted that U.S. corporate taxes declined from 4.4 per cent of GNP in 1961 to 4.2 per cent in 1963, and that they are expected to decline further—to less than 4 per cent—as a result of the Revenue Act of 1964.

<sup>8</sup> The small difference between corporate taxes as a per cent of GNP in the United States and other industrial countries may come as a surprise. Corporate tax rates in most industrial countries are in the range of 40 per cent to 52 per cent, so that, even as a per cent of corporate profits, U.S. corporate taxes in 1960 were not much higher than in other industrial countries. Thus a large part of the difference between the ratio of corporate taxes to GNP shown in Table 3 for the United States and for other countries is due to the larger proportion of GNP produced in the corporate sector in the United States. The basic point, however, is that the ratio of corporate profits to GNP is everywhere so small that even substantial differences in rates of corporate tax can result in only small differences in ratios of corporate taxes to GNP.

#### IV. *Conclusions*

The ratio of corporate profits to GNP is less than 2 percentage points higher in the United States than in other major industrial countries. If all countries abolished their corporate profits tax, or if the U.S. corporate tax rate were reduced so that corporate tax revenue relative to GNP were about the same in the United States as in these other countries, or if all countries were permitted to rebate corporate taxes paid on export sales (as they do for indirect taxes), U.S. prices would be unlikely to decline relative to export prices of other major industrial competitors by more than 2 per cent.<sup>9</sup> And because this tax shift may induce an increase in the domestic price level, the relative decline in U.S. export prices may be less than 2 per cent if the corporate tax is replaced by an indirect tax.

If the United States could act unilaterally and eliminate the corporate tax while other countries kept theirs, the improvement of the U.S. competitive position would be greater. The relative decline in U.S. export prices might be as much as 4 or 5 per cent if the U.S. price level remained unchanged. If, as seems more likely, the U.S. price level increased, the decline in U.S. export prices relative to price levels in other countries would be smaller.

\* The balance-of-payments impact of a shift from the personal income tax to an indirect tax can be analyzed with this same approach. There is a smaller presumption of a gain in U.S. export competitiveness, both because it is probable that a switch from the personal income tax to an indirect tax would raise domestic prices more than a switch from the corporate tax would, and because personal income taxes as a per cent of GNP are not much higher in the United States than in the major industrial competitors.

# PATTERN OF INCOME DISTRIBUTION IN AN UNDERDEVELOPED ECONOMY: A CASE STUDY OF INDIA

By P. D. OJHA AND V. V. BHATT\*

It is generally believed that the pattern of income distribution is more unequal in an underdeveloped economy than in a developed one.<sup>1</sup> Recently Simon Kuznets [3] collected the available evidence with regard to the income distribution pattern in some developed and underdeveloped countries, and this evidence seems to support the hypothesis about greater income inequality in the underdeveloped countries than in the developed countries. This evidence also includes the estimates on the pattern of income distribution in India.

The estimates on the income distribution pattern in the underdeveloped countries, however, are not very reliable, and the estimates about India, in particular, are based on highly inadequate data and involve some questionable assumptions [6] [7].<sup>2</sup> Recently, more adequate and reliable data and estimates relating to national income, consumers' expenditure, earnings of agricultural and industrial labor, population, saving, etc., have become available in the case of India; some of these data are not available even for some developed countries. Since India represents one of the largest underdeveloped economies, and since it is now possible to estimate fairly reliably the pattern of her income distribution, it would be interesting to find out whether the conclusion reached by Kuznets about the greater in-

\*The authors are, respectively, fiscal expert with the International Monetary Fund, Washington, D.C., and development economist with the Asian Institute for Economic Development and Planning, United Nations, Bangkok. The views expressed represent the authors' personal views.

<sup>1</sup> See W. Arthur Lewis [4, pp. 226-28]. Lewis, of course, recognizes that it is difficult to generalize in this matter because of the differences among the underdeveloped countries as well as among the developed countries.

<sup>2</sup> The estimates by Mukherjee and Ghosh are based on very inadequate data. Lydall uses the income tax data as well as the consumers' expenditure data; however, he has not examined the reliability of consumers' expenditure data for any single year. Furthermore, his estimates are based on population projections that have turned out to be incorrect. Lydall combines the tax data and the consumers' expenditure data on the assumption that the Pareto "Law" of the distribution of incomes applies in India to the same extent as it does in most other countries. His data, incidentally, show far less concentration than the data of the Mukherjee-Ghosh study and thus do not fit Kuznets' general conclusions.

For a detailed reference to the available data and their limitations, see [8].

equality in income distribution in the underdeveloped countries than in the developed countries is borne out in the case of India.

It is the object of this paper to estimate the pattern of income distribution in India on the basis of all available data and to compare it with the pattern in some of the developed economies during recent years as well as during the earliest historical period for which estimates are available. This comparison shows, as will be seen in detail later, that the pattern of income distribution is less unequal in India than in some of the developed countries. Even the distribution of posttax income is only slightly more unequal in India than in the United Kingdom and the United States, and it is less unequal than in Denmark, Netherlands, and Sweden. For the earlier historical period for which estimates are available, the pattern in the developed countries was much more unequal than that which prevails at present in India.

In Section I, estimates relating to the pattern of income distribution in the rural and urban household sector as well as in the aggregate household sector in India are presented for the period 1953-54 to 1956-57.<sup>3</sup> The Indian pattern is compared, in Section II, with the patterns in some of the developed countries during recent years as well as for the earliest historical period for which data are available, and with some of the underdeveloped countries for a recent period. Some of the conclusions emerging from this study are presented in Section III.

### *I. Pattern of Income Distribution in India*

For the purpose of this study, the income-receiving unit is taken to be the household and not the individual.<sup>4</sup> This study attempts to present the pattern of income distribution in the household sector only, which comprises households, noncorporate businesses (including the agricultural sector), and private collectives like temples, educational institutions, and charitable foundations. The household sector thus includes all sectors other than the corporate and the government sector.

The household sector<sup>5</sup> is divided into three income groups: (a) households with an annual income equal to or below Rs. 3,000 (which is the income-tax-exemption limit), defined as belonging to the *low-income group*; (b) households with an annual income between Rs.

<sup>3</sup> These are fiscal years April to March.

<sup>4</sup> Pattern of income distribution based on individual income recipients would be misleading. See in this connection Titmuss [9, Chs. 2 and 4].

<sup>5</sup> The National Sample Survey (on the basis of which the estimates are made in this study) defines a household as "a group of persons usually living together and taking principal meals from a common kitchen." See [2, pp. 1-2].

3,001 and Rs. 25,000; and (c) households with an annual income above Rs. 25,000. The (b) and (c) households are described as belonging to the *high-income group*, while only the (c) households are referred to as the *top-income group*. The low-income-group households are subdivided into ten income groups corresponding to the consumers' expenditure brackets of the National Sample Survey. Thus in all there are twelve income groups.

The high-income-group households are divided into three functional groups: (a) salary-earner group; (b) nonsalary-earner group, including proprietors and partnership business concerns; and (c) farm household group. Incomes earned by private collectives are treated as belonging to the high-income nonsalary-earner group; this would introduce an upward bias in the estimate of the level of per-household income in this group. However, since the incomes of private collectives are not likely to form a significant proportion of the income of the nonsalary-earner group, no substantial error would be introduced in the estimate.

The household sector is also divided into (a) rural households and (b) urban households. The availability and the degree of reliability of the relevant data have largely determined the period—1953-54 to 1956-57—selected for this study. Again, in view of the quality of the available data, this period is divided into two parts; Period I relates to years 1953-54 to 1954-55, and Period II relates to years 1955-56 to 1956-57.

The method of estimation is described in detail in our article in the *Reserve Bank of India Bulletin* [8]. From that, it would be clear that a variety of sources has been used to obtain the required data. These different sets of data may not be mutually consistent, and they may have different degrees of reliability. Inevitably certain assumptions had to be made while combining these different sets of data. The results of this study, therefore, should not be taken as definitive; they indicate fairly reliably, however, the *structure* of income distribution among various income groups.

On the basis of the estimated pattern of income distribution, Lorenz curves were drawn. Table I is based on the Lorenz charts and gives income (both personal and disposable) accruing to the top 5 per cent of households and each decile group of households during 1953-54 to 1956-57.<sup>9</sup>

The top decile accounts for 28 per cent of personal income, while the bottom decile obtains only 3 per cent; the top 5 per cent of households accounts for 20 per cent of personal income. The distribution

pattern of disposable income is more or less similar to that of personal income. The concentration ratio<sup>7</sup> for disposable income is only slightly lower (0.335) than that for personal income (0.340); direct taxes seem to affect only the top 5 per cent.

Income distribution is more uneven in the urban sector than in the rural sector; the urban sector concentration ratio for personal income is 0.400, while this ratio for the rural sector is only 0.310.

Though the concentration ratio for personal income declined slightly from Period I to Period II because of the change in the distribution pattern in the rural sector, the concentration ratio in the urban sector actually increased from 0.378 during Period I to 0.421 during Period II (Table 2). It was only in Period II that a substantial acceleration in capital formation under planned development took place [1], particularly in the urban sector, and this seems to have made the pattern of income distribution more uneven in the urban sector. Again, this increase in the concentration ratio in the urban sector is associated with a rise in the saving-income ratio in the urban sector and hence in the aggregate household sector; the saving-income ratio in the urban sector rose from 12.5 per cent during Period I to 19.5 per cent during Period II.

top 10 per cent in personal income seem to be similar in the underdeveloped countries (excepting Ceylon and Mexico) and in the developed countries; the share of the top 5 per cent in these countries ranges between 20 per cent to 25 per cent, while the share of the top 10 per cent is between 30 per cent and 35 per cent. Only in Mexico and Ceylon do their shares go beyond these ranges. It is, however, significant that in India the shares of the top 5 per cent and the top 10 per cent are the lowest among these 12 countries.

Similarly, though there are not very sharp differences between the shares of the bottom 20 per cent in the developed and the underdeveloped countries (excluding India), its share in India is the highest among the 12 countries.

The average concentration ratio in five underdeveloped countries (excluding India and counting Mexico twice) is higher (0.47) than that for six developed countries (0.42), indicating a more uneven distribution pattern in the underdeveloped countries (Table 4). However, the concentration ratio in India (0.34) is lower than in all the developed countries except the United Kingdom. Even with regard to the distribution of disposable (posttax) income, the concentration ratio in India is lower than those in the Netherlands, Denmark, and Sweden.

Of course, the disparity between the concentration ratio of the distribution of personal income and that with regard to disposable income is much wider in the developed countries than in the underdeveloped countries like India; this indicates the greater effectiveness and scope of the system of direct taxes in reducing the degree of inequality in income distribution in the developed countries.

The historical data on income distribution patterns in some of the developed countries are shown in Table 5 for the earliest period for which such data are available. These data indicate a much greater degree of inequality in income distribution in the developed countries at an earlier stage of their economic development than that which prevails at present in these countries as well as in India. Probably in the earlier stages of economic development, the pattern of income distribution becomes more uneven, and the trend towards greater equality establishes itself only after a certain stage in economic development is reached. If this is true, the distribution pattern in India may become more unequal as development proceeds; the rise in the concentration ratio in the urban sector in Period II may indicate this trend.

The picture with regard to the distribution pattern in India as compared to that in the developed countries is altered somewhat when a comparison is made for the rural/agricultural and urban/nonagricul-

tural sector separately. Table 6 gives these concentration ratios in the rural and the urban sectors in nine countries. The Indian concentration ratio in the urban sector is lower than that in Ceylon, Puerto Rico, and Poland, but is higher than that in Germany, Netherlands, Sweden, and the United States; this shows that the distribution pattern in the urban sector is more uneven in India than in the developed countries.

In the rural sector, the concentration ratio in India is the lowest among the seven countries (except Germany and the Netherlands). Probably there is not as much difference in the distribution pattern in the rural sector as between the developed and the underdeveloped countries as there is between countries with large-scale and highly capital-intensive farm industry and those with small-scale and less capital-intensive farm industry.

In any case, the Indian data confirm the general trend in most of the countries towards a greater degree of inequality in income distribution in the urban sector than in the rural sector. Only the United States and Italy show a different picture. The estimates for the United States for earlier periods were in conformity with the general trend; the recent experience, as Kuznets suggests [3, pp. 53-54], may be due to a rise in the shares in total agriculture of the South and the West, both of which show wide inequality in the distribution of farm income, the former because of the cleavage between Negroes and whites, and the latter because of the cleavage between large-scale capital-intensive farms and smaller units.

### III. *Concluding Observations*

This comparative study of the income distribution pattern in India and some of the developed countries leads to the following tentative conclusions; these conclusions are inevitably tentative because of the possibility of a large degree of error in the estimates with regard to India as well as some of the developed countries.

1. The pattern of income distribution in India is more or less similar to the patterns in some of the developed countries and is more even than the patterns in some of the underdeveloped countries and the pre-1930 patterns in some of the developed countries.

2. However, the distribution pattern in the urban sector seems to be more uneven in India than in some of the developed countries, and the trend seems to be towards an increase in the degree of inequality in income distribution in the urban sector in India.

3. In the rural sector, there seems to be much less difference between the distribution pattern in the developed countries and the underdeveloped countries than that between countries with large-scale capital-intensive agriculture and those with less commercialized and less capital-intensive agriculture.

4. As in some of the developed as well as the underdeveloped countries, in India, too, the distribution pattern in the rural sector is more even than the pattern in the urban sector.

5. The generalization about greater unevenness in the distribution pattern in the underdeveloped countries than in the developed countries does not seem to be valid in the light of the Indian distribution pattern. It is true, however, that the system of direct taxes is more effective in the developed countries in reducing the degree of inequality in income distribution than it is in the underdeveloped countries; the disparity between the concentration ratios with regard to personal and disposable (posttax) income is much wider in the developed countries than in the underdeveloped countries.

# CAPITAL THEORY AND THE RATE OF RETURN

## *A Review Article*

By EDWARD F. DENISON\*

The three lectures in the volume under review<sup>1</sup> consolidate and extend Robert Solow's previous examination of the relationship between capital and economic growth. What is crucial is to know the social rate of return on investment; this is the principal theme, and a sound one.

Readers of Solow's articles on capital and growth will surely wish to continue with this book. It is also a particularly good introduction to the discussion; prepared for oral delivery, the presentation seems easier to follow than his previous contributions. It would be an injustice, however, to imply that these lectures are merely one more contribution to the current debate over capital and growth; they are more than that. This review can scarcely suggest the breadth of the discussion or the elegance of the theoretical analysis and manipulation of simple models; suffice it to say that the whole volume is highly stimulating even where, as it seemed to the reviewer, it goes wrong.

The first lecture begins by asking why capital theory is in so unsettled a state. One cause is that capital has many forms and several characteristics, and different writers stress different aspects. There is no reason to suppose a "single object called 'capital' can be defined to sum up in one number" all the facts about time lags, gestation periods, and all the different kinds of capital goods. Solow's prescription for progress is to narrow the issues by concentrating on the causes and consequences of saving and investment. Because the consequences are so important, the "central concept in capital theory should be the rate of return on investment," which yields an unambiguous answer to "almost any important planning question . . . about the saving-investment process." That appraisal of the effect of investment on output requires some form of rate of return seems almost a truism. Yet much empirical analysis is based on capital-output ratios or incremental capital-output ratios. Solow's comment that the only way one can make any sense out of these ratios is to suppose they are meant as crude approximations to rates of return, and that, if that is indeed the intent, economists have an obligation to do better, is not unneeded.

Solow states that rates of return on investment can be calculated without measuring the capital stock. The point would be as important as Solow con-

siders it if it meant that the difficulties that haunt measurement of capital can also be avoided. This, unhappily, is possible neither in theory nor in statistical practice. Consider even the computation of a one-period rate of return in Solow's simplest models. Solow has a planning authority consider alteration of some initial plan by reducing consumption (and raising investment) in period 0 in order to raise consumption in period 1. Computation of the rate of return, he finds, requires only comparison of the additional consumption foregone in period 0 with the additional consumption made possible in period 1. But the latter is after depreciation; the capital stock must be left as well able to provide for future production as in the initial plan. The replacement of capital required to keep the stock at the end of period 1 at the level envisaged by the initial plan must therefore be known. Measurement of the additional consumption allowable in period 1 thus encounters every complexity faced in measuring the capital stock; they can be measured equally well—as in Solow's case of only one capital good which evaporates at a known constant rate—or equally badly in more complicated cases. When in Lecture 3 Solow computes a rate of return for the real world, he must also have a capital stock value to replace consumption foregone in period 0.

In Lecture 2 Solow introduces "technical progress," shows how to calculate rates of return in simple models in which progress is, and is not, embodied in structures and equipment, and states his preference for the embodied model. He also shows that if private and social rates of return are equal in the absence of technical progress, they will also be equal with technical progress, whether it is embodied or disembodied (unless one adopts the Arrow postulate "that technical progress arises out of experience and experience consists of gross investment"). In other words, "the mere fact of embodied technical progress does not itself drive a wedge between the private and social rates of return, if there were no wedge before." He argues, however, that in the embodied model the rate of return falls short of the conventionally calculated net marginal product of capital by obsolescence. Emphasis here must be on Solow's special conception of the term "conventionally calculated"; no modification of accepted theory or practice, which have always taken account of obsolescence, seems to the reviewer to be involved.

Lecture 3 calculates social rates of return at high employment in the United States and West Germany on the assumption of full embodiment of productivity increases in capital goods. Though results are presented with diffidence, caution, and alternatives, his preferred estimates for the United States are likely to be quoted and used. This reviewer considers (1) they are much too high on Solow's assumption that all technical progress is embodied, and (2) that the embodied model itself is unreasonable.

Solow's estimates for the United States refer, initially, to the private domestic business sector, excluding housing. He uses the Cobb-Douglas production function with all productivity change embodied in capital that he presented in his May 1962 *AER* paper. He calculates  $\alpha$ , the elasticity of GNP in this sector with respect to capital, for each of several assumed values of  $\lambda$ , the rate of quality improvement in capital. The former paper provided estimates for values of  $\lambda$  from .00 to .04; the present volume adds estimates of  $\alpha$  for  $\lambda$  equals .05. As  $\lambda$  goes up,  $\alpha$  goes down, and  $R^2$  goes up.

Solow says the proper  $\lambda$  in principle is that which provides the highest  $R^2$ , but all are so high that the only available criterion for choosing one value of  $\lambda$  rather than another is observed distributive shares. He views the  $\alpha$  of .36 obtained with  $\lambda$  at .05 as close to the property share in the relevant sector of GNP, and hence as satisfactory. The value of  $Q$ , potential GNP in this sector, is put at \$302 billion in 1954. At  $\lambda$  equals .05, the model throws off a 1954 value of \$309 billion for  $J$ , the value of structures and equipment when old capital is equated with new by its productivity. He computes a "gross" rate of return as  $\alpha Q/J$ , which equals .35. From this .04 is deducted for depreciation and .05 for obsolescence. Another .05 is deducted because  $\alpha$  includes the earnings of inventories, but  $J$  excludes their value. (No mention is made of the need for a similar, but larger, deduction for land.) This leaves .21 as the net rate of return on business capital at high employment in 1954. Inclusion of housing, he estimates, would lower it to .18. The housing reduction seems only half enough, but I shall examine only the 21 per cent rate of return excluding housing.

The actual share of capital obviously is a decisive determinant of the results. Solow, relying on the distribution of corporate gross national product, says "in reasonably prosperous years since 1929" employee compensation has amounted to 64 per cent of corporate gross product at market prices and 70 per cent at factor cost, and suggests that, the choice being uncertain, an  $\alpha$  between .30 and .36 would be appropriate. But surely market prices are irrelevant; there is no reason to count indirect taxes as capital income and little to think that they even fall disproportionately on property income. On the other hand, the corporate profits tax, treated in national accounts as a tax on profits, must in some degree (if only in regulated industries) be shifted. Hence the share of gross property income in corporate GNP at factor cost provides a maximum, not a minimum, estimate. This share in point of fact has not been as high as .30 since 1951. I think .29 is the highest one could take as representative of high employment in 1954.

If one relies on factor shares, there is no need to experiment with a range of  $\lambda$ s, as Solow does. The correct one is uniquely determined by the assumptions of full embodiment and a Cobb-Douglas production function. Full embodiment means that the increase in capital each year is, by definition, the amount that keeps output proportional to total factor input at high employment. The index of capital should be so measured every year, yielding identical indexes for output and input. Since Solow actually uses an average  $\lambda$  for all years, however, I illustrate the calculation by using average growth rates for the 1929-57 period, based on  $\alpha = .29$ .

Solow (p. 82) gives a growth rate of .5 per cent for man-hours. The increase in man-hours therefore contributed .5 times the .71 labor share, or .35 points to the growth rate of  $Q$ , which Solow gives as 3. This leaves 2.65 points as the contribution of capital. Working backwards, we can divide this by the capital share of .29 to obtain 9.1 per cent a year as the growth rate of quality-adjusted capital, Solow's  $J$ . In this model  $J$  *must* include land and inventories, since their earnings are included in  $\alpha$  and they are not counted as separate inputs. Solow gives the growth rate for conventionally measured structures and equipment as 2.1 per cent. We can obtain 1.8 as the weighted-average

growth rate for all conventionally measured capital if we take the growth rate of land as 0 and that of inventories as 1.8; allocate the gross capital share of .29 as .04 for land, .04 for inventories, and .21 for structures and equipment (my rough estimates); and use gross income shares as weights for the growth rates in computing the average. Since the average age of structures and equipment is almost the same in 1929 and 1957, we can subtract 1.8 from 9.1 and obtain 7.3 per cent (.073 as Solow would express it) for  $\lambda$ . This is the average rate of quality improvement for structures, equipment, land, and inventories combined. The rate of return implicit in the model is also readily approximated. Solow gives the dollar value of  $J$  only for values of  $\lambda$  up to .05, but by extrapolating his results we may estimate that, when  $\lambda$  is .073,  $J$  as he measures it, covering structures and equipment, is about \$245 billion. Goldsmith's estimates of nonresidential land and inventories in the relevant sectors are about \$125 billion and \$100 billion, respectively, so the total  $J$  is about \$470 billion.  $Q$  remains \$302 billion. Following Solow, depreciation is .04 and obsolescence, equal to  $\lambda$ , is .07, giving .11 of the value of structures and equipment for the two together. The high-employment net rate of return in 1954 from this model is therefore about  $[(.29 \times 302) - (.11 \times 245)] \div 470$  or .13, which compares with the .21 calculated by Solow. Over half the difference is due to Solow's ignoring land, and the rest to the net effect of his use of a higher  $\alpha$  and lower  $\lambda$ . The 13 per cent rate of return at *high employment* implied by full embodiment is not, perhaps, *prima facie* unreasonable for 1954, but I shall try to show that the full-embodiment assumption is.

Technical progress is supposed to be embodied only in structures and equipment. The  $\lambda$  of .073 computed from the model is lowered because it includes inventories and land; without them it would be at least .101. If the shares and growth rates cited in the previous paragraph are used, it can be readily computed that conventionally measured labor, land, and inventories together account for only .43 points in the growth rate, leaving 2.57 as the contribution of structures and equipment. With  $\alpha$ , referring to structures and equipment alone, at .21, division yields a growth rate for  $J$  referring to structures and equipment of 12.2 per cent. The growth rate of conventionally measured structures and equipment was 2.1, so  $\lambda$  for structures and equipment is 10.1 per cent (.101). But this in fact underestimates the  $\lambda$  implied by the assumption of full embodiment. The breakdown of property income given above distributed net earnings by asset values (separately within agriculture and other industries) with the net value of structures and equipment based on customary obsolescence rates. With  $\lambda$  at .101 or more, obsolescence would be greater, the current values of structures and equipment therefore much smaller,  $\alpha$  therefore less than .21, and  $\lambda$  therefore much greater than .101.

Both the fully embodied model and the usual calculations obtain the rate of return as the ratio of earnings to net stock. The fully embodied model implies a higher rate of obsolescence than presumably has been customary in business or national income accounting, hence lower values for both net earnings and net stock. Whether it yields a higher or lower rate of return depends on the composition of the stock; my calculations suggest that, not surpris-

ingly, any difference is not enormous. Nonetheless, the question of whether this is a useful approach to the rate of return rests on whether it is reasonable to suppose the rate of obsolescence is above 10 per cent a year on the value of all structures and equipment combined, including office buildings, hammers, and desks as well as computers. Solow originally carried his  $\lambda$  only up to 4 per cent and still has gone only to 5, probably not above the obsolescence rates implicit in some of the usual estimates. A rate above 10 must therefore not have seemed likely to him (the comparison seems legitimate since Solow discusses  $\lambda$  as referring only to structures and equipment though it actually includes other capital); the implied net value of structures and equipment, well under \$200 billion in 1954, seems implausibly low; and the underlying assumption that output per unit of conventionally measured input changes *only* from changes in the quality of capital goods is not really tenable. The knotty problems of measuring capital consumption and net stock cannot be solved by taking the extreme assumption.

Solow states he rejects private rates of return as usually calculated in favor of his production function because he is "after bigger game"—the social rate of return. But his production function, selected so as to make  $\alpha =$  the capital share, does not help him. All five sources of possible divergence between private and social rates of return that he lists refer either to the measurement of national product or to aspects of property income measurement other than obsolescence, and are handled identically in the usual income-stock ratio and in his production function.

Solow himself gives enough reasons why his German production functions, fitted to 1925-38 and 1950-57 data for the entire economy, cannot be satisfactorily compared with the American, and others can be inferred from what I have said. In addition, Rolf Krenzel's work shows that any production function using 1950-55 data that does not take account of the elimination of imbalances in the capital stock during this period could hardly be usable.

## A Graphical Proof of the Impossibility of a Positively Inclined Demand Curve for a Factor of Production

The mathematical impossibility of a positively inclined demand curve for a factor of production, under conditions of perfect competition in both the factor and product markets, has been irrefutably established.<sup>1</sup> However, to the mathematically unsophisticated, this theoretical conclusion remains somewhat mystical or at least unsubstantiated by a more graphic analysis. It is, indeed, difficult to reconcile this central theorem of economic theory with the salient (albeit anomalous) case of a positively sloped demand curve for a consumer's good.<sup>2</sup> And the layman's scepticism is not easily allayed by the common explanation that the firm's reaction to a factor price change involves nothing comparable to the consumer's income effect (which, when negative, makes the positive slope feasible); for the contention that the "only 'production effect' is something similar in character to the substitution effect" [1, p. 90] is not wholly accurate—the firm's "scale effect" (i.e., the effect exercised on the demand for a factor by a change in the level of output that is itself consequent to the factor price change) is, at least conceptually, analogous to the consumer's income effect. The crucial question that must be asked (and which has been answered mathematically) is not whether the theory of the firm involves something similar to the consumer's income effect (for it does), but whether this scale effect can be negative.

It is because of the incomplete understanding of the economic underpinnings and implications of this mathematical proof that the problem of positively sloped factor-demand curves is neglected in most nonmathematical presentations of microeconomic theory; and where such analyses have been attempted, they have been fallacious. A prime example of misconceived graphical expositions of the "law of factor demand" is that committed by Professor Hicks himself in *Value and Capital* [1]. In Figure 1 (similar to Hicks's Figure 20, p. 90) is drawn the production function for the case of one input,  $A$ , and one output,  $X$  (ignore, for the moment, the broken lines). The line  $K_1P$  has a slope equal to the ratio of the factor price to the product price; hence, equilibrium is given by the point of tangency of  $K_1P$  and the production function, point  $P$ . (At this point the price ratio equals the marginal product of  $A$ ; that is, the factor price equals the value of the marginal product of  $A$ .)

<sup>1</sup> Cf. J. R. Hicks [1, pp. 320-22] and P. A. Samuelson [2, pp. 76-78].

<sup>2</sup> Even in the case of consumer theory it is seldom realized that if the consumer has a convex preference-ordering, the demand curve for a commodity can only increase with a rising price over a limited price range. From its uppermost intersection with the price axis, the demand curve must initially have a negative slope and might then double back toward the price axis to accommodate a positive slope.

A decline in the price of  $A$  is represented by a diminution in the slope of  $K_1P$  to that of, e.g.,  $K_2P'$  and a new point of tangency at  $P'$ . Because of the convexity (from above) of the production function (which is a prerequisite for equilibrium in the first place), the quantity employed of the factor  $A$  must necessarily increase to accommodate the new equilibrium. This result is perfectly general (under the assumption of perfectly competitive markets) *for the case where only one factor is employed by the firm*. However, as a next

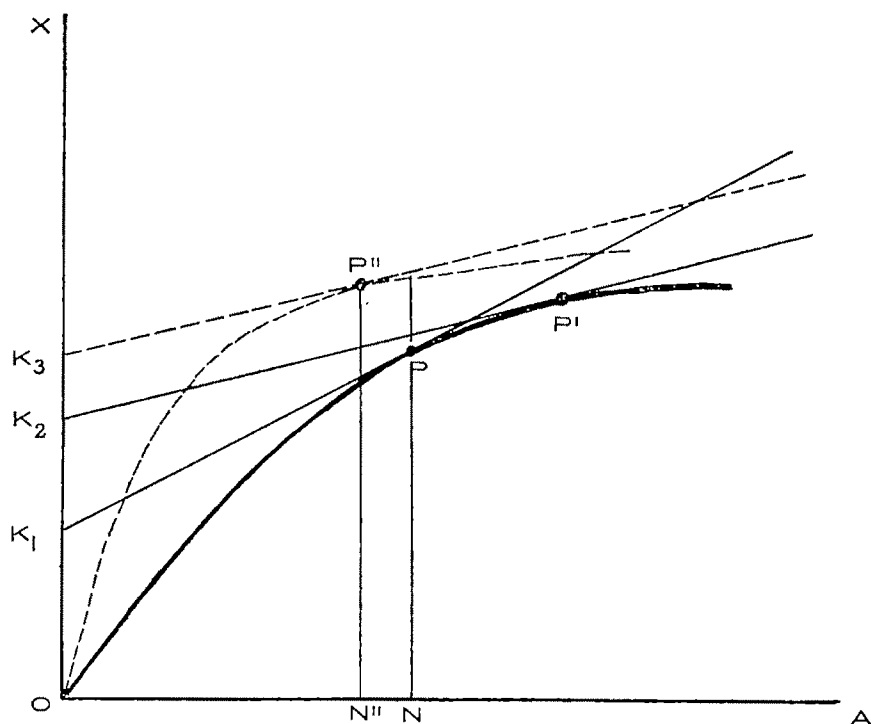

FIGURE 1

step in his analysis, Hicks [1, p. 93] supposes that "the firm produces one product  $X$ , and employs two factors,  $A$  and  $B$ . Then, since the relation connecting the amounts of factors and the amount of product still has the same sorts of properties as those to which we are accustomed, the demand for  $A$  must necessarily expand when its price falls." Abstracting from the mathematical appendix, this is a *non sequitur*. When there are two (or more) factors, there is a family of production functions for (any) one factor, each pertaining to a fixed amount of the other factor(s). Thus, the production function in Figure 1 is drawn on the assumption that the quantity of  $B$  is fixed. But it certainly does not make sense to assume that the quantity of  $B$  employed by a profit-maximizing firm will be unchanged when the quantity of both input  $A$  and output  $X$  are increased. Thus the new equilibrium will

probably be located on a different production function. And the textual analysis of Hicks does not negate the feasibility of a new equilibrium at  $\bar{P}'$  where  $K_s P''$  (parallel to  $K_s P'$ ) is tangent to the higher production function, and where the quantity of  $A$  has decreased (that this situation can be contrived on an isoquant map will be shown shortly). Obviously a more sophisticated graphical analysis is needed.

In the following analysis<sup>3</sup> we continue to assume perfect competition in both the factor and product markets. We also assume that the firm combines two factors of production,  $A$  and  $B$ , according to a production function which is representable by a convex set of isoquants, to produce one commodity (see Figure 2a). Labeled  $Y_1$ ,  $Y_2$ , and  $Y_3$  are iso-revenue curves (that is, isoquants valued at the given product price); the price line (or equal-cost line) labeled  $P_1$  has a slope equal to the negative of the ratio of the price of  $A$  to the price of  $B$  (the latter price also denoted  $P_1$ ). Equilibrium is, of course, given by the tangency point  $s$  where  $Oa_3$  and  $Ob_1$  of  $A$  and  $B$ , respectively, are employed. A decline in the price of  $A$  (with the product price and factor  $B$  price remaining unchanged) is represented by a diminution in the slope of  $P_1$  to, e.g.,  $P_2$ . If the firm were subject to an expenditure constraint, it would operate at point  $t$ , which clearly could be either to the left or right of point  $s$ . However, unlike the household, the profit-maximizing firm does not impose such a constraint upon itself; consequently, the lower marginal cost will induce the firm to expand its output<sup>4</sup> (and, under the assumption of perfect competition, the increase in revenue will be proportionate to the increase in output). Hence, the new equal-cost line will be higher than  $P_2$ , e.g.,  $P_2'$ .

From the knowledge contained in this diagram, we cannot say whether the quantity of  $A$  will increase or decrease; if the appropriate iso-revenue curve were  $Y_3'$ , then  $A$  would increase to  $Oa_4$ , but if the curve were  $Y_3$ , then  $A$  would decrease to  $Oa_2$ . However, the feasibility of this latter possibility is not established by this diagram because it does not represent the entire profit-maximizing process, but only depicts those conditions which must hold on the expansion path. The superstructure of the profit-maximizing process is represented in Figure 3 where the price of the factor is equated to the value of its marginal product,  $VMP_A$ . The horizontal lines represent the given prices of  $A$  corresponding to price lines  $P_1$  and  $P_2$  in Figure 2a. At the original price,  $P_1$ ,  $Oa_2'$  of  $A$  is purchased, and when the price is reduced to  $P_2$ , if the  $VMP_A$  curve remained stable, then  $A$  would increase to  $Oa_3'$ . However, the  $VMP_A$  curve is drawn on the assumption of a fixed quantity of input  $B$ , and it is doubtful that this latter quantity would be invariant with respect to changes in the quantity of  $A$  employed. Indeed, under the conditions for a positively inclined demand curve established in Figure 2a, it is obvious that the quantity of  $B$  purchased must increase; i.e., since point  $v$  must lie on the price line,  $P_2'$ , if it is to lie to the left of a vertical line through  $s$ , it must also lie above a horizontal line through  $s$ .

<sup>3</sup>Since the analysis is largely heuristic, perhaps the word "proof" should properly be eschewed in disclamation of mathematical rigor.

<sup>4</sup>This follows obviously from the assumption of a horizontal marginal-revenue curve and from the necessity (for an equilibrium) of an upward-sloping marginal-cost curve.

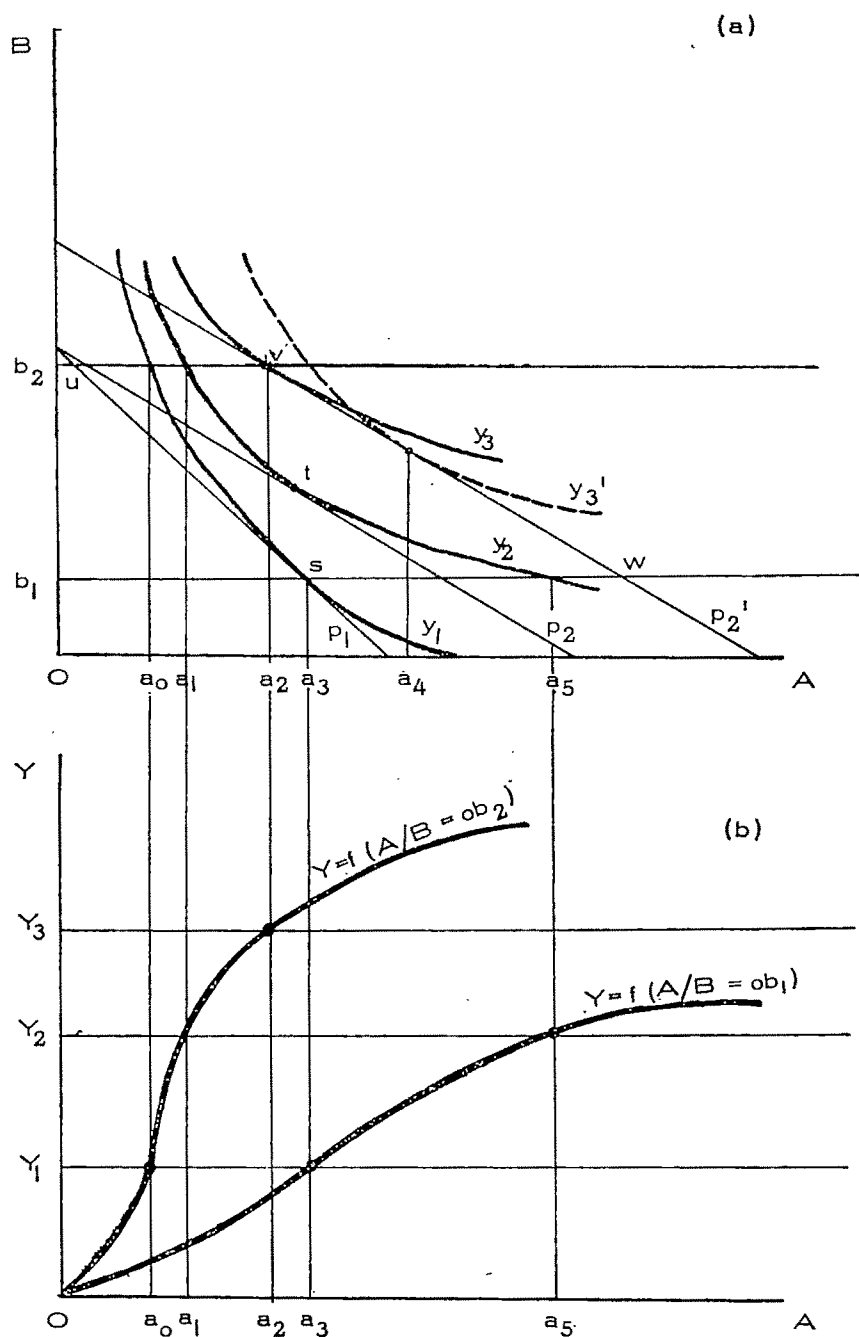

FIGURE 2

Most economists<sup>5</sup> assume that if the amount of  $B$  used in the production process is increased,  $VMP_A$  will increase. If this were universally true, then the new  $VMP_A$  curve would be represented by, e.g.,  $VMP_2$  in Figure 3, and the quantity of  $A$  purchased by the firm would invariably increase (to  $Oa_4'$  in Figure 3) as a result of a price decrease. However, in order to show that this assumption is not universally valid, it is only necessary to contrive an

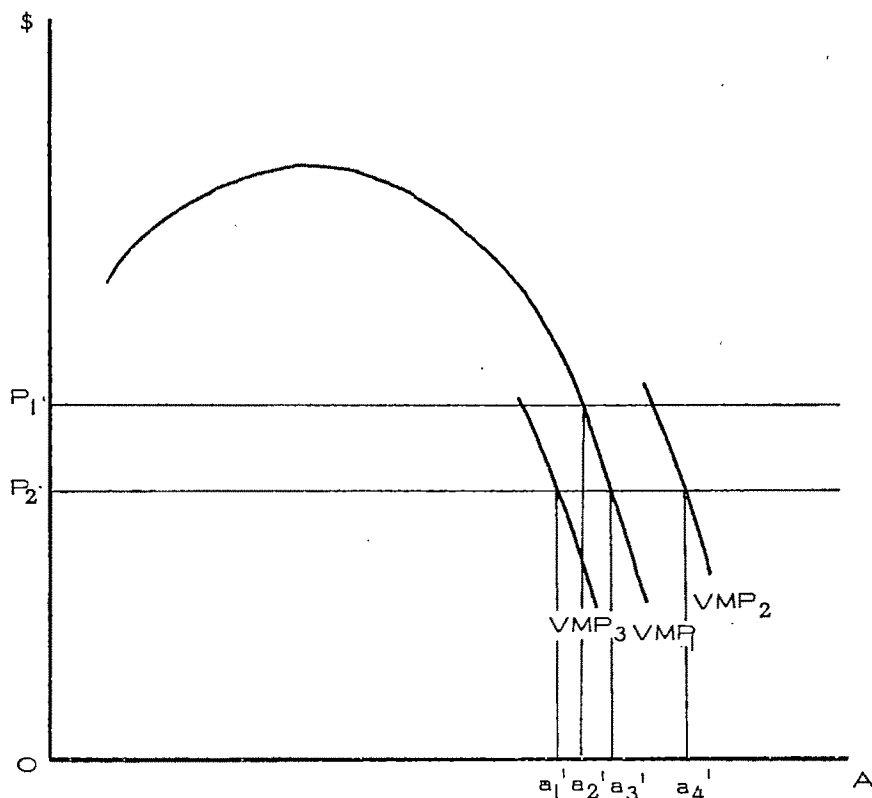

FIGURE 3

isoquant (or iso-revenue) map in which the level of the  $VMP$  curve of one factor is inversely related to the quantity employed of the other factor. In Figure 4a is constructed such a map; *over the relevant range of output*, the  $VMP_A$  curve corresponding to  $Ob_1$  of  $B$  is higher than the  $VMP_A$  curve corresponding to  $Ob_2$  of  $B$ . This point is clarified by the derivation, in Figure 4b, of two total-revenue curves respective to quantities  $Ob_1$  and  $Ob_2$  of  $B$ .<sup>6</sup> Since

<sup>5</sup> Cf. G. J. Stigler [3, p. 189].

<sup>6</sup> The iso-revenue map is drawn to yield total-revenue curves without diminishing returns to facilitate comparison of the slopes, but we could just as easily derive curves with diminishing returns.

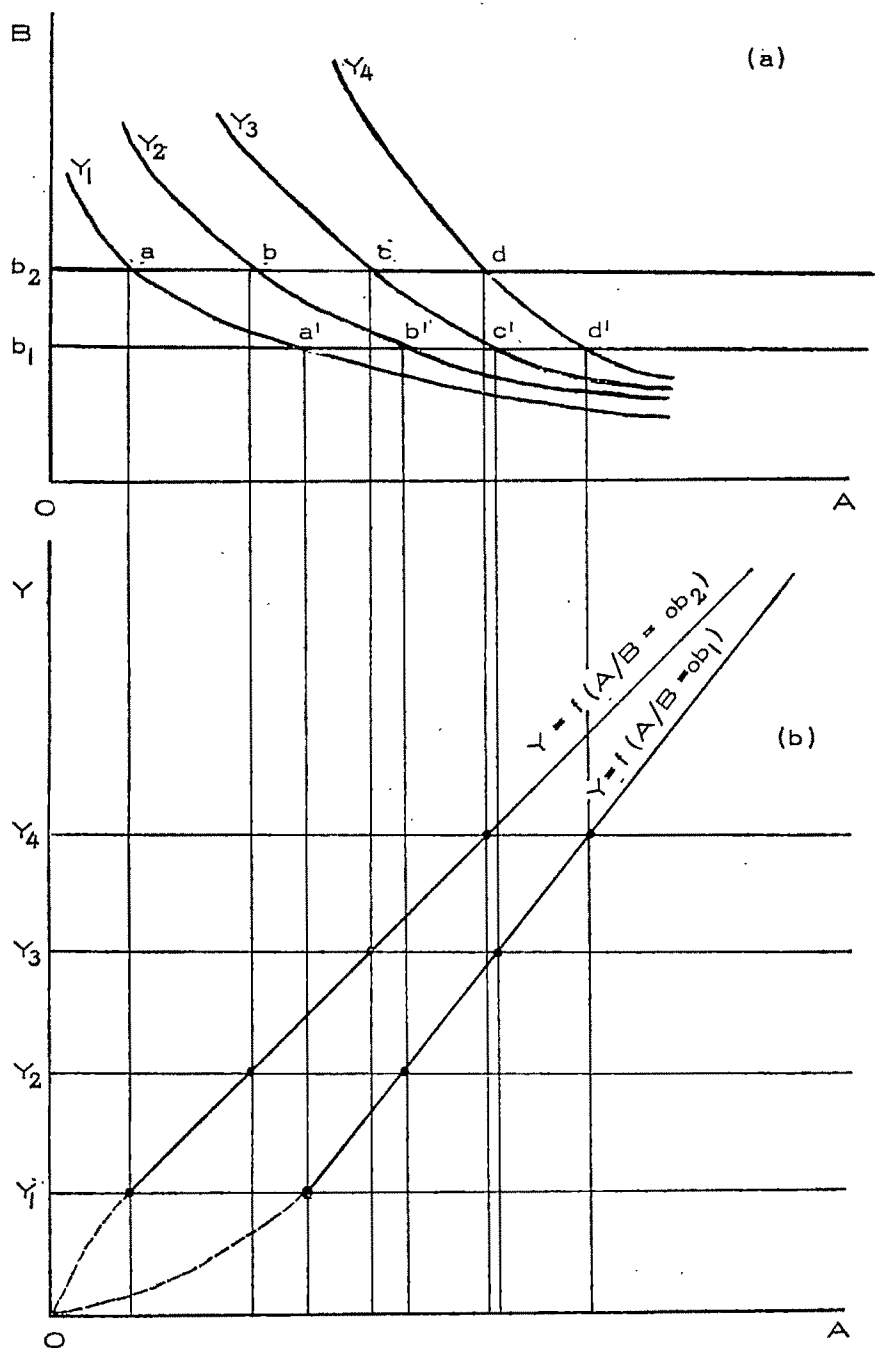

FIGURE 4

$ab > a'b'$ ,  $bc > b'c'$ , etc., the slope (i.e., the  $VMP_A$ ) of the total-revenue curve derived with  $B = Ob_2$  is smaller than the slope of the total-revenue curve drawn with  $B = Ob_1$ . Consequently, the profit-maximizing conditions in Figure 3 do not, in themselves, preclude the possibility that the lower price of  $A$  will lead to a shift in the  $VMP_A$  curve to, e.g.,  $VMP_3$  with a reduced quantity,  $Oa_1'$ , of  $A$  satisfying the new equilibrium.

Thus, independent examination of the expansion-path equilibria and the superficial profit-maximizing process has in each case failed to vitiate the feasibility of a positively sloped demand curve for a factor, but has in each case established conditions (manifested in the shape of the iso-revenue map) that must hold for such a phenomenon to occur. It is necessary now to ask whether these two conditions are compatible with each other. A cursory comparison will indicate that they are fundamentally contradictory and incompatible. For the total-revenue curves in Figure 2b, derived from the iso-revenue map in Figure 2a, reveal a steeper slope, or larger  $VMP_A$ , when  $B = Ob_2$  than when  $B = Ob_1$ ; and this, of course, is in sharp contradistinction to the case of Figure 4. We can easily show that any iso-revenue map which can accommodate a positively inclined demand curve necessarily implies that the level of the  $VMP$  curve of one factor is directly related to the quantity employed of the other factor by demonstrating that the horizontal distance between  $Y_1$  and  $Y_2$  in Figure 2a is greater when  $B = Ob_1$  than when  $B = Ob_2$ . When  $B = Ob_2$ , the *maximum* horizontal distance between  $Y_1$  and  $Y_2$  is  $uv$ . The *minimum* distance between these iso-revenue curves when  $B = Ob_1$  is  $sw$ , which must be greater than  $uv$  since the (absolute) slope of  $P_1$  is greater than the (absolute) slope of  $P_2$ . Hence, the minimum distance between the two curves when  $B = Ob_1$  is necessarily greater than the maximum possible distance when  $B = Ob_2$ . This conclusion, of course, requires our assumption of convex iso-revenue curves, and holds, *a fortiori*, under the case of strict convexity depicted in the diagram. Thus, the superficial profit-maximizing conditions require an isoquant map, or production function, that is fundamentally different from the production function required by the expansion path conditions—each has an unorthodox skew, but in opposite directions.<sup>7</sup> We conclude, then, that the demand curve for a factor of production, under conditions of perfectly competitive factor and product markets, must have a negative slope for all ranges of output.

### Professor Samuelson on Theory and Realism

In a discussion of "Problems of Methodology" at an AEA meeting [4], Paul Samuelson embarks on a critique of theories which employ unrealistic assumptions. He concludes with this strong indictment of "unrealistic, abstract models": "If the abstract models contain empirical falsities, we must jettison the models, not gloss over their inadequacies" [4, p. 236].

Let us first indicate how Samuelson reaches this judgment. He defines a theory "as a set of axioms, postulates, or hypotheses that stipulate something about observable reality [4, p. 233]. Denoting the theory as  $B$ , the "consequences" derived from it as  $C$ , and the "assumptions" antecedent to it as  $A$ , he argues that  $A$ ,  $B$ , and  $C$  must actually be identical in meaning, mutually implying one another. Thus, he holds, if the assumptions are empirically false, and the theory therefore unrealistic, the deduced consequences cannot possibly be empirically valid. In other words, an unrealistic theory cannot yield realistic consequences.

Samuelson also considers the possibility that the assumptions are *wider* than the theory, and that the theory is *wider* than the consequence, so that there is a subset  $C-$  of  $C$ , while  $A$  is a subset of  $A+$ . In this case  $A+$  may imply  $B$ , without  $B$  implying  $A+$ ; and  $C$  may imply  $C-$ , without  $C-$  implying  $C$ . If  $C-$  happens to be empirically valid, does this "validate" the wider theory  $B$ , or the even wider set of assumptions,  $A+$ ? Samuelson explicitly rejects this. He regards as "nonsense" the claim that the validity of  $C-$  justifies holding an unrealistic theory  $B$ , let alone the completely unwarranted set of assumptions  $A+$ .

What Samuelson does here is to reject *all theory*. A theory, by definition, is much wider than any of the consequences deduced. If the consequences were to imply the "theory" just as the theory implies the consequences, that theory would be nothing but another form of the empirical evidence (named "consequence") and could never "explain" the observed, empirical facts.

In addition, Samuelson errs in another way. We never deduce a consequence from a theory alone. We always combine the postulated relationships (which constitute the theory) with an assumption of some change or event and then we deduce the consequence of the *conjunction* of the theoretical relationships and the assumed occurrence. Thus, we do not infer  $C$  or  $C-$  from  $B$ , but rather from the conjunction of  $B$  and some occurrence  $O$ . If  $C-$  can be deduced from  $B$  *cum*  $O$ ; and if both  $O$  and  $C-$  are found to *correspond* to data of observation which can be regarded as the empirical counterparts (referents, proxies) of the theoretical  $O$  and  $C-$ ; then we rule that the theory  $B$  has sustained the test. This test does not prove that  $B$  is "true," but we have no reason to "jettison"  $B$ —unless we have a better theory  $B'$ .

Let us now leave aside the argument by which Samuelson reached his decision against "unrealistic, abstract models" and theories; let us, instead, confront Samuelson's judgment with Samuelson's pattern of theorizing when

he discusses, not methodology, but substantive propositions of economics. Let us choose the brilliant performance with which he demonstrated an important proposition in the theory of international trade.

In his ingenious papers on international factor-price equalization [2] [3], Samuelson shows "that free commodity trade will under certain specified conditions, *inevitably* lead to *complete* factor-price equalisation" [2, p. 181]. He admits that "it would be folly to come to any startling conclusions on the basis of so simplified a model and such abstract reasoning," but he submits—very rightly, in my opinion—that "strong simple cases often point the way to an element of truth present in a complex situation" [2, p. 181].

What are his assumptions, hypotheses, conditions? Here is the list:

1. There are but two countries, America and Europe.
2. They produce but two commodities, food and clothing.
3. Each commodity is produced with two factors of production, land and labour. The production functions of each commodity show "constant returns to scale". . . .
4. The law of diminishing marginal productivity holds. . . .
5. The commodities differ in their "labour and land intensities". . . .
6. Land and labour are assumed to be qualitatively identical inputs in the two countries and the technological production functions are assumed to be the same in the two countries.
7. All commodities move perfectly freely in international trade, without tariffs or transport costs, and with competition effectively equalizing the market price-ratio of food and clothing. No factors of production can move between the countries.
8. Something is being produced in both countries of both commodities with both factors of production. . . .

From this he concludes: "Under these conditions, real factor prices must be exactly the same in both countries (and indeed the proportion of inputs used in food production in America must equal that in Europe, and similarly for clothing production)" [2, p. 182].

In his "intuitive proof" he goes so far as to state this: "I have *established unequivocally* the following facts:

Within any country: (a) a high ratio of wages to rents will cause a definite decrease in the proportion of labour to land in both industries; (b) to each determinate state of factor proportion in the two industries there will correspond one, and only one, commodity price ratio and a unique configuration of wages and rent; and finally, (c) that the change in factor proportions incident to an increase in wages/rents must be followed by a one-directional increase in clothing prices relative to food prices" [clothing being the more labor-using commodity, food the more land-using commodity] [2, p. 187].

It may be fair to state that Samuelson had characterized the problem as "a purely logical one" [2, p. 182]. But he sometimes uses language of empirical operations, for example, when he speaks of "observing the behaviour of a representative firm." It should be clear, however, that what he "observes"

is merely the logical consequence of a set of assumptions; that the "behaviour" is purely fictitious; and that his representative firm is only an ideal type, a theoretical construct. Let me quote the sentence: "... if we observe the behaviour of a representative firm in one country it will be exactly the same in all essentials as a representative firm taken from some other country—regardless of the difference in total factor amounts and relative industrial concentration—provided only that factor-price ratios are really the same in the two markets" [2, pp. 187-88, emphasis supplied].

At the end of his discussion Samuelson evaluates some important qualifications which he finds help to "reconcile results of abstract analysis with the obvious facts of life concerning the extreme diversity of productivity and factor prices in different regions of the world" [2, p. 196]. These "qualifications" to the theorem furnish Samuelson with the "causes" of the factor-price diversities. In other words, he does not hesitate, quite rightly in my view, to explain the observed facts of life—factor-price differentials—by the divergences of real conditions from the ideal ones which form the basis of the factor-price equalization theorem.

Would the Samuelson of the *A-B-C* argument against unrealistic, abstract models approve of the Samuelson of the intuitive proof of the factor-price equalization theorem? Frankly, I do not know. Perhaps both Samuelsons make a distinction between a theorem and a theory, meaning by the former a proposition deduced from counterfactual assumptions and postulates, and by the latter a proposition stipulating something about observable reality. But the Samuelson of the *Foundations of Economic Analysis*, who preceded both other Samuelsons, did pledge allegiance to a program emphasizing "the derivation of operationally meaningful theorems" [1, p. 3].

Since, according to Samuelson, a theorem deduced from counterfactual hypotheses cannot yield empirically true consequences, and does not contain operationally defined terms, it is not immediately clear just what an "operationally meaningful theorem" is supposed to be. If it is supposed to be a "strong simple case" pointing the way to "an element of truth present in a complex situation" [2, p. 181], then we have no quarrel. For, I submit, this is what the bulk of economic theory does. It is based on counterfactual assumptions, contains only theoretical constructs and no operational concepts, and yields results which, we hope, point to elements of truth present in complex situations. To call such theorems "operationally meaningful" is to confer on them a designation which is slightly deceptive; but in any case it gives them the recognition which Samuelson, as critic of the Friedman position, or "the F-twist," wants to deny.

I conclude that Samuelson, one of the most brilliant theorists in present-day economics, produces his best work when he deduces from unrealistic assumptions general theoretical propositions which help us interpret some of the empirical observations of the complex situations with which economic life confronts us.

## Theory and Realism: A Reply

1. The art of jujitsu is to direct your opponent's strength against himself. As I read Fritz Machlup's attempt to use my earlier writings on international factor-price equalization and on operationally meaningful theorems to annihilate my recent contention that the contrafactual content of a theory is its shame and not its glory, I am all admiration for his pretty footwork. Indeed I feel like the friend of Abraham Lincoln, who said he could have foregone the pleasure of being run out of town on a rail if it weren't for the honor of it.

But the issue is a serious one, and I must record the impression that, after examining Machlup's argument, I see no reason to change my view or to acknowledge any inconsistency between my precept and my practice.

2. Let the issue be clear. No one expects that anything be *perfect*, much less a simplified theory. All scientists settle for some degree of approximation; and, by gad, they had better! However, the whole force of my attack on the F-twist (which I believe is not well rendered by the first sentence that got quoted from my paper) is that the doughnut of empirical correctness in a theory constitutes its worth, while its hole of untruth constitutes its weakness. I regard it as a monstrous perversion of science to claim that a theory is *all the better for its shortcomings*; and I notice that in the luckier exact sciences, no one dreams of making such a claim.

In connection with slavery, Thomas Jefferson said that, when he considered that there is a just God in Heaven, he trembled for his country. Well, in connection with the exaggerated claims that used to be made in economics for the power of deduction and a priori reasoning—by classical writers, by Carl Menger, by the 1932 Lionel Robbins (first edition of *The Nature and Significance of Economic Science*), by disciples of Frank Knight, by Ludwig von Mises—I tremble for the reputation of my subject. Fortunately, we have left that behind us. Still there is no reason to encourage tolerance of falsification of empirical reality, much less glorify such falsification.

3. My position is so innocuous as to be platitudinous. Yet from it, Machlup believes, must follow a rejection by me of all theory. (In my copy the last two words are double-underlined!) He says: "A theory, by definition, is much wider than any of the consequences deduced." By whose definition? Machlup's? God's? Webster's? Well, not by mine—as those who read my earlier note will have seen. And I have to confess to an even sharper disagreement with Dr. Machlup on this issue.

Scientists never "explain" any behavior, by theory or by any other hook. Every description that is superseded by a "deeper explanation" turns out upon careful examination to have been replaced by still another description, albeit possibly a more useful description that covers and illuminates a wider area. I can illustrate by what everyone will agree is the single most successful "theory" of all time. I refer to Newton's theory of universal gravitation.

Kepler's ellipses gave better descriptions of the planets than did the epicycles of the Greeks. Newton showed that second-order differential equations relating the accelerations of bodies to the inverse square of their distances from neighboring bodies could still better *describe* astronomical observations. After Newton had described "how," he did not waste his time on the fruitless quest of "why?" but went on to run the Mint and write about religion. Nor has anyone since Newton provided "the explanation."

The second greatest achievement of scientific theory was Maxwell's formulation of electromagnetism. Heinrich Hertz, the great discoverer of radio waves, made my methodological point in the strongest terms when he said, "All of Maxwell's theory boils down to the simple question of whether the observable measurements on light and waves do or do not satisfy Maxwell's partial differential equations."

My third and final example illustrates how a stubborn fact can kill a pretty theory. Mercury's orbit never quite agreed with Newtonian gravitation. An F-twister would have said: "So much the worse for the fact. The theory is even the better for its inadequacy." That, of course, is rot. One would not jettison Newton's theory until a better one was found to replace it, for the very good reason that Newton did describe many facts *correctly*. But any specialist on the perihelion of Mercury would prefer to use mechanical extrapolations to reliance on the false theory. Then along came Albert Einstein. His special theory of relativity described well (but did not "explain") a host of facts, including the perihelion of Mercury. For velocities small compared to the speed of light, Newton's theory came close to duplicating Einstein's. But when the factual chips were down, the simpler Newtonian equations had to be replaced by the Einstein-Lorenz equations *because the facts called for this*.

4. About my 1948 factor-price equalization analysis I can be brief. From certain empirical hypotheses taken as postulates, by cogent logic I *deduced* as theorems certain other empirical properties. After the demonstration, the implications were obvious. When one looks at the complicated real world, one finds it obvious that the hypotheses of the syllogism are far from valid; and, also, the consequences are far from valid. This is indeed a matter for regret and full disclosure of inaccuracy should be made. Nevertheless, and here I imagine Dr. Machlup and I for once will agree, a strong polar case like this one can often shed useful light on factual reality.

Thus, writing before the Marshall Plan and at a time when many were despairing of Europe's future, I was led by my factor-price model to make the diffident suggestion that moving goods by trade might be able to do nearly as much for living standards as moving Europeans to Australia and elsewhere. Any validity to such a lucky insight would have to be attributed to the degree

of realism of the model, and I can only pray for my brain children that they be ever more realistic.

5. Since the emphasis of my *Foundations of Economic Analysis* on "operationally meaningful theorems" has been brought up, it gives me the opportunity to use my strength against my friendly critic. The doctrines of revealed preference provide the most literal example of a theory that has been stripped down to its bare implications for empirical realism: Occam's Razor has cut away every zipper, collar, shift, and fig leaf. In 1938 I had shown that the regular theory of utility maximization implied, for the two-good case, no more and no less than that "no two-observed points on the demand functions should ever reveal the following contradiction of the Weak Axiom":

$$\begin{aligned} P_1^a Q_1^a + P_2^a Q_2^a &> P_1^a Q_1^b + P_2^a Q_2^b \\ P_1^b Q_1^b + P_2^b Q_2^b &> P_1^b Q_1^a + P_2^b Q_2^a \end{aligned}$$

In *Foundations*, I showed that the complete theory of regular utility for any number of goods could be exhausted by the empirical hypothesis that the following Slutsky-Hicks matrix of compensated-substitution terms be singular, symmetric, and nonpositive definite of rank  $n-1$ . I.e., the demand functions  $Q_i = Q_i(P_1, \dots, P_n, I)$  satisfy

$$S = [S_{ij}] = \left[ \frac{\partial Q_i}{\partial P_j} + Q_j \frac{\partial Q_i}{\partial I} \right] = [S_{ji}]$$

$$\sum_{j=1}^n S_{ij} P_j = 0$$

$$\sum_1^n \sum_1^n S_{ij} P_i P_j x_i x_j < 0 \quad \text{for } x_i \neq \lambda P_i, \quad \lambda \neq 0$$

In 1950, Professor H. S. Houthakker, in a brilliant maiden work, strengthened the Weak Axiom to show that the whole conventional theory, for any number of goods, boils down (aside from obvious regularity conditions of continuity and smoothness) to the testable requirement that one never observe the following contradiction of the Strong Axiom:

$$\sum P^a Q^a > \sum P^a Q^b, \quad \sum P^b Q^b > \sum P^b Q^c, \dots, \sum P^s Q^s > \sum P^s Q^a.$$

I beg that Dr. Machlup take me literally and seriously when I assert that the conventional theory has *no* wider implications than these prosaic factual implications. Once the two formulations had been rigorously proved to imply each other mutually, that issue was settled.

6. The F-twist, in the crude form set up and massacred by me, represents an unlamented lost cause. Let me conclude by mentioning some genuinely puzzling methodological problems that Dr. Machlup and I might continue to argue about fruitfully.

a. Quine, Polanyi, Kuhn, Hanson,<sup>1</sup> and other students of science have

<sup>1</sup> W. V. O. Quine, *From a Logical Point of View* (New York, 1961), Ch. 2, "Two Dogmas of Empiricism"; M. Polanyi, "Tacit Knowing," *Reviews of Modern Physics*, Oct. 1962, 34, 601-16; T. Kuhn, *The Structure of Scientific Revolutions* (Chicago 1962); N. R. Hanson, *Patterns of Discovery* (Cambridge, U.K. 1961).

been propounding variants of the view that what is a fact (and what is a truism!) is a very subjective thing. While I should guess that much of this discussion involves a confusion between the psychological problem of forming scientific notions and the valid findings of science, undoubtedly there are deep problems here that need further study.

b. Scientists constantly utilize parables, paradigms, strong polar models to help understand more complicated reality. The degree to which these do more good than harm is always an open question, more like an art than a science.

c. Finally, in some areas at least, Nature seems to show an inexplicable simplicity. This is a brute fact, more or less of a bonus, which if it had not existed could not have been expected. As a result, the working scientist learns as a matter of routine experience that he should have faith that the more beautiful and more simple of two equally (inaccurate) theories will end up being a more accurate describer of wider experience.

This bit of luck vouchsafed the theorist should not be pushed too far, for the gods punish the greedy.

### Diminishing Returns and Linear Homogeneity: Comment

In a recent issue of this journal, G. Warren Nutter [3] has provided a mathematical specification of a production function which seeks to justify the practice common in many price theory books of drawing the short-run product curve with a point of inflection *and* a maximum point, while assuming the long-run curve to involve constant returns to scale. He cites as the reason for his communication part of my footnote invitation to those who draw the curve in this way to *specify* their function [2, p. 126, n. 3] and a statement by Professors Stonier and Hague [5, p. 229] in which they flatly assert that the marginal product of the variable factor will always diminish when returns to scale are constant. (Both my footnote and its context make clear that a maximum point is also contemplated.)

Although Nutter implies that my view is identical to that of Stonier and Hague, he is wrong: My position is simply that "a thorough search of the literature has failed to reveal a single case in which a writer has *specified* a linearly homogeneous production function which produces such a total product curve." Nor has Nutter cited any examples. Indeed it can be done, but he, too, is unsuccessful in his *ex post* attempt to specify a function which will produce diagrams such as those contained in George Stigler's book [4, p. 115, Fig. 46] or in Richard Leftwich's book [1, p. 111, Fig. 34; p. 124, Fig. 36], which may presumably be taken as representative examples. Both depict the short-run curve as having a maximum point.

Nutter's entry, which he asserts is representative of a family which does exist and makes economic sense, is:

$$(1) \quad x = 22a^{1/4}b^{3/4} - 20a^{1/2}b^{2/3},$$

with the first and second partial derivatives:

$$(2) \quad \frac{\partial x}{\partial b} = \frac{66a^{1/4}}{4b^{1/4}} - \frac{40a^{1/3}}{3b^{1/3}}$$

$$(3) \quad \frac{\partial^2 x}{\partial b^2} = -\frac{66a^{1/4}}{16b^{5/4}} + \frac{40a^{1/3}}{9b^{4/3}}$$

In these equations,  $x$  is output, and  $a$  and  $b$  are inputs. [Shinsuke Horiuchi has pointed out that the exponent of  $b$  in the second term on the right in equation (3) should be  $4/3$  and not  $3/4$ .]

Nutter states that "if  $a=1$ , equations (1) and (2) are positive for all  $b \geq 0.998$ ." This must mean that, when  $a=1$ , total product continues to increase without limit as long as the variable input increases beyond  $b=0.998$  because  $\partial x/\partial b$  remains positive. Thus *his* short-run product curve has *no* maximum point.

Nutter's equation is of the general form:

$$(4) \quad x = Aa^tb^{1-t} - Ba^ub^{1-u},$$

where  $t$  and  $u$  are positive fractional exponents, each less than unity. In general, in the case of equation (4),  $x$  will have a zero value when

$$(5) \quad b = a \left[ \left( \frac{B}{A} \right)^{1/(u-t)} \right].$$

The general formula for the marginal product of  $b$  is

$$(6) \quad \frac{\partial x}{\partial b} = (1-t)Aa^tb^{-t} - (1-u)Ba^ub^{-u}.$$

This partial derivative will be equal to zero when

$$(7) \quad b = a \left[ \left( \left( \frac{1-u}{1-t} \right) \left( \frac{B}{A} \right) \right)^{1/(u-t)} \right].$$

Letting  $b_0$  represent the value of  $b$  at which  $x=0$ , and  $b_1$  represent the value of  $b$  at which  $\partial x/\partial b=0$  in equations (5) and (7) respectively, it follows that

$$(8) \quad b_1 = b_0 \left[ \left( \frac{1-u}{1-t} \right)^{1/(u-t)} \right].$$

In equation (8), if  $u > t$ , the term in parenthesis will be less than unity, but the exponent will be greater than unity; and if  $u < t$ , the term in parenthesis will be greater than unity, but the exponent will be negative (with an absolute value greater than unity). Thus, in equation (8), the base raised to the power will always be less than unity, unless  $u=t$ . Accordingly,  $b_1$  will be less than  $b_0$  in every case except that in which  $u=t$ . It follows, therefore, that the marginal product of  $b$ , or  $\partial x/\partial b$ , will always attain a

zero value at a lower level of input of the variable factor than that at which the total product, or  $f(x)$ , attains its zero value, except when  $u=t$ . In the latter case, both attain a zero value at the same level of input. Moreover,  $\partial x/\partial b$  will be negative for all values of  $b$  less than the complex term on the right in equation (7) and positive for all values of  $b$  greater than that term. It follows, therefore, that  $f(x)$  will generally have a minimum point at a negative level of output (whatever that may mean in economic terms) but that it has no maximum point.

Since Nutter's function has no maximum point, it can hardly serve as the mathematical basis of the curves depicted in books like those mentioned above. What Professor Nutter has done is to provide a linearly homogeneous production function with a point of inflection on the short-run product curve, but, in the process, he has eliminated the point of negative marginal returns to the variable factor (the Point of Absolutely Diminishing Returns). Thus, in the case of his family of functions, what is ordinarily described as Stage II, the Stage of Diminishing Average Returns to the Variable Factor, never ends.

Nor is this all. Although his statement "if  $a=1$ , equations (1) and (2) are positive for all  $b>0.998$ " is true enough and indicates that his function has no maximum, the statement is quite meaningless. Since, in Nutter's equations  $u>t$ , not only do these two equations become positive at *different* values of  $b$ , but also, because of the values of the constants specified by him, neither becomes positive when  $b=0.998$ . His statement can be made about any values of  $b>0.319$ . Equation (2) is equal to zero when  $b=0.07756$  and positive thereafter, while equation (1) is equal to zero when  $b=0.319$  and positive thereafter. These *two* values differ too greatly from each other and from Nutter's *single* value of 0.998 to allow explanation of the difference as a minor arithmetical error.

Moreover, Nutter also asserts [3, p. 1085]:

... equation (3) is positive for  $2.45>b>1$  and negative for  $b\geq 2.45$ . Of course, over the range at which  $b$  has increasing returns,  $a$  has a negative marginal product. That is,

$$\frac{\partial x}{\partial a} < 0 \quad \text{for } 1 < b/a < 2.45.$$

Not only is this statement wrong, but the upper numerical value ( $b/a=2.45$ ) is the value at which his *second partial derivative* is equal to zero. The incorporation into the statement of *this* value clearly shows that he has fallen into the elementary error of confusing the *direction* of movement of the *marginal* product of the variable input, on the one hand, with its *sign* and with its *magnitude* relative to that of the *average* product of the variable input on the other. The nature of his mistake can be made clear by reference to Euler's Theorem, which, of course, applies to linearly homogeneous functions.

The theorem states:

$$(9) \quad x = \frac{\partial x}{\partial a} a + \frac{\partial x}{\partial b} b,$$

and by dividing both sides by  $b$  and transposing the terms, we have

$$(10) \quad \frac{x}{b} - \frac{\partial x}{\partial b} = \frac{\partial x}{\partial a} \frac{a}{b}.$$

Since  $a$  and  $b$  are inputs and  $x$  is output, and all three are always positive in the relevant discussion, so are  $a/b$  and  $x/b$  always positive. The sign of  $\partial x/\partial a$  thus depends upon the sign (not on the direction of movement) of  $\partial x/\partial b$  and upon the relative magnitudes of  $x/b$  and  $\partial x/\partial b$ . The term  $x/b$  is, of course, the average product of the variable factor. Equation (10) discloses that whenever  $\partial x/\partial b$  is negative,  $\partial x/\partial a$  must be positive. Moreover,  $\partial x/\partial a$  will be positive when  $\partial x/\partial b$  is positive only if  $\partial x/\partial b$  is less than  $x/b$ ; and  $\partial x/\partial a$  will always be negative when  $\partial x/\partial b$  is both positive and greater than  $x/b$ .

It happens in the case of Nutter's function that, when  $\partial x/\partial b$  is positive and increasing, it is also greater than  $x/b$ . But, it is clearly true in the case of his function that  $\partial x/\partial b$  is also positive and greater than  $x/b$  for part of the range in which  $\partial x/\partial b$  decreases and that  $\partial x/\partial a$  is negative up to the point at which  $\partial x/\partial b = x/b$ .

Making use of Nutter's equations and constants, I have produced the results shown in Table 1. This table clearly demonstrates the nature of his errors. It shows that not only is Nutter's lower limit for  $\partial x/\partial a < 0$  incorrect, but also that his upper limit is wrong. Since the marginal and average products of the variable input are approximately equal when  $b=9.98$ , he should have written

$$\begin{aligned} x &< 0 && \text{for } 0.319 < b/a \\ \partial x/\partial a &< 0 && \text{for } 0.000 < b/a < 9.98. \end{aligned}$$

The values in Table 1 also disclose that Nutter's function produces a curve which is different from those contained in the books cited previously. When  $x$  is measured on the vertical axis and  $b$  is measured on the horizontal axis, his function produces a short-run product curve which begins at the origin, falls below the origin, with  $x$  becoming ever more negative until  $b=0.07756$ , and then begins to rise, with  $x$  becoming ever less negative until  $b=0.319$ , where the curve crosses the  $b$  axis. The value of  $x$  then increases at an increasing rate as  $b$  increases, until  $b=2.45$ , and, eventually, the value of  $x$  increases without limit at a decreasing rate. Admittedly, the table does not show the value of  $x$  beyond the point at which  $b=1,000,000,000,000$  when  $a=1$ .

Nutter completes his communication by stating this conclusion at the end of his comment [3, p. 1085]:

The essential point is that the condition of linear homogeneity in a production function does not, in and of itself, rule out areas of short-run increasing returns (or negative marginal products) to some inputs.

If this is *the* essential point, Nutter has said nothing new. In the sentence in my book [2, p. 126] immediately following the one to which I have at-

tached the footnote—which is partly quoted in Nutter's comment—I have said:

It follows from Euler's Theorem and the fact that the production function is assumed to be linearly homogeneous that, whenever the marginal product of  $a$  is greater than the average product of  $a$ , the marginal product of  $b$  *must* be negative [italics in the original].

(In my example  $a$  is the variable input.)

And, on page 133 of the book, I have repeated for the benefit of the careless or untrained reader:

... As we have already seen, if total product or output ( $X$ ) increases proportionately as all inputs are increased proportionately, the case involves constant returns to scale, and the production function is linearly homogeneous. As we have already also seen, this type of production function is not inconsistent with the principles of increasing or diminishing marginal or average returns to the variable factor, for even though output increases proportionately as inputs are increased proportionately, this fact alone does not require or result in a situation in which output changes proportionately *when one factor only is changed* and others are held constant [italics in the original].

The preceding quotation speaks for itself. Indeed, since the publication of Nutter's comment, I have received from Ryuzo Sato a copy of a brilliant paper concerning the stability of growth equilibrium (to be published in *Econometrica*) which he delivered at the December, 1963 meeting of the Econometric Society. This paper contains a new and quite general formulation of linearly homogeneous production functions. Some of the forms of the Sato function do, in fact, produce short-run total product curves having points of inflection as well as maximum points, while others do not. Nutter's equation is merely a special case of the Sato function. As far as I know,

Sato is the first to produce a general equation of this type, and, although he utilizes it in the context of growth problems, one by-product of his work is that he has also met a need long existing in the literature of price theory.<sup>1</sup>

#### Diminishing Returns and Linear Homogeneity: Comment\*

In his comment on G. Warren Nutter's note, H. H. Liebhafsky refers to my production function, the one exhibiting short-run total product curves which have points of inflection as well as maximum points. This function is

$$(1) \quad Y = F(K, L) = \frac{K^2 L^2}{b_0 L^3 + b_1 K^3}, \quad b_0 > 0, \quad b_1 > 0,$$

where  $Y$  = total product,  $K$  = capital, and  $L$  = labor. When

$$\frac{L}{K} = \sqrt[3]{\frac{2b_1}{b_0}},$$

the marginal product of labor becomes zero, and when

$$\frac{L}{K} = \sqrt[3]{\frac{b_1}{2b_0}},$$

the marginal product of capital becomes zero. Furthermore, since

$$F''\left(1, \frac{L}{K}\right) < 0 \quad \text{for} \quad \left[\frac{b_1(7-3\sqrt{5})}{2b_0}\right]^{1/3} < \frac{L}{K} < \left[\frac{b_1(7+3\sqrt{5})}{2b_0}\right]^{1/3},$$

short-run diminishing returns set in when  $L/K$  is equal to

$$\left[\frac{b_1(7-3\sqrt{5})}{2b_0}\right]^{1/3}.$$

As Liebhafsky mentions, I used the above function to illustrate the stability conditions of growth equilibrium ("On the Stability of Growth Equilibrium" presented at the 1963 meeting of the Econometric Society). In fact, equation (1) is a special case of a general linear homogeneous function,

$$(2) \quad Y = \left[ aL^{-\alpha} + \sum_{i=0}^n b_i K^{-\beta_i} L^{-(\alpha-\beta_i)} + cK^{-\alpha} \right]^{-1/\alpha}.$$

In the above equation when  $a=c=0$ ,  $b_i=0$  (except for  $i=0$  and  $i=1$ ),  $\alpha=1$ ,  $\beta_0=2$  and  $\beta_1=-1$ , then equation (2) turns out to be equation (1). And also in equation (2), when  $a=c=0$ ,  $b_0=22$ ,  $b_1=-20$  and  $b_i=0$  ( $i=2, 3, \dots, n$ ),  $\alpha=-1$ ,  $\beta_0=-\frac{1}{4}$ , and  $\beta_1=-\frac{1}{3}$ , then we obtain Nutter's equation. When all  $b_i=0$ , then we get the constant-elasticity-of-substitution (CES) function.

I used equation (2) to illustrate the production function represented by equation (1) as well as to illustrate a production function in which the elasticity of substitution is always positive (the positive-elasticity-of-substitution function).

### Diminishing Returns and Linear Homogeneity: Comment

Professor Nutter shows that constant returns to scale and increasing marginal productivity are not mutually exclusive properties of a production function. But, while his production function displays these two properties, it differs in two important respects from the "traditional" production function<sup>1</sup> with which all students of economics are familiar.

The Nutter production function is:

$$(1) \quad x = 22a^{1/4}b^{3/4} - 20a^{1/3}b^{2/3}$$

where  $x$  is output and  $a$  and  $b$  are inputs of two productive services. Differentiating with respect to  $a$  and  $b$ , the marginal products of the productive services are found to be:

$$\begin{aligned} \frac{\partial x}{\partial a} &= \frac{22}{4} a^{-3/4} b^{3/4} - \frac{20}{3} a^{-2/3} b^{2/3} \\ \frac{\partial x}{\partial b} &= \frac{66}{4} a^{1/4} b^{-1/4} - \frac{40}{3} a^{1/3} b^{-1/3}. \end{aligned}$$

Holding  $a=1$  and varying  $b$ , we find the following deviations from the "traditional":

<sup>1</sup> See, for example, R. H. Leftwich, *The Price System and Resource Allocation* (New York 1960), p. 124.

1. Output is negative if  $0 < b < .3113$  even though the inputs of both productive services are positive.

2. If  $.01385 < b < 2.447$  the marginal product of  $b$  is positive and rising with increases in  $b$  and the marginal product of  $a$  is negative. This is the result sought. But the function is not symmetrical, for there is no area within which the marginal product of  $a$  is positive and falling with increases in  $b$  while the marginal product of  $b$  is negative.

A production function which conforms to the "traditional" is:

$$(3) \quad x = \frac{a^2 b^3}{.5a^3 + .5b^3}$$

where, again,  $x$  is output and  $a$  and  $b$  are inputs of two productive services.<sup>3</sup> Differentiating, we find,

$$(4) \quad \begin{aligned} \frac{\partial x}{\partial a} &= \frac{ab(b^4 - .5a^3b)}{(.5a^3 + .5b^3)^2}, \\ \frac{\partial x}{\partial b} &= \frac{ab(a^4 - .5ab^3)}{(.5a^3 + .5b^3)^2}. \end{aligned}$$

This function displays constant returns to scale, positive output for all positive combinations of inputs of the two productive services, and (holding  $a=1$  and varying  $b$ ) the familiar marginal product curves. Specifically:

1. If  $0 < b < .5265$  the marginal product of  $b$  is positive and increases with increases in  $b$  while the marginal product of  $a$  is negative.

2. If  $b > 1.898$  the marginal product of  $a$  is positive and decreases with increases in  $b$  while the marginal product of  $b$  is negative.

<sup>3</sup> This is a representative of a family of production functions described by:

$$x = \frac{a^\alpha b^\alpha}{ga^{2\alpha-1} + (1-g)b^{2\alpha-1}}$$

which includes special cases of the Cobb-Douglas ( $\alpha=.5$ ) and CES ( $\alpha=1$ ) production functions. If  $\alpha > 1$ , areas of increasing marginal productivity result.

### Diminishing Returns and Linear Homogeneity: Comment

In many respected textbooks<sup>1</sup> there will be found the opinion that increasing marginal productivity of a variable input and linear homogeneity of the production function are incompatible. This error may result from failure to write down algebraic functions that fulfill both criteria. G. Warren Nutter [8] has now given a linearly homogeneous function that has an initial region of increasing marginal returns to the variable input. Another such function with first increasing marginal returns was mentioned by Karl Menger [7, pp. 25-56; esp. p. 30]. But the two functions of Menger and Nutter are not representative of the "law of diminishing returns" that has dominated economic thought since Serra and Turgot, particularly in the well-known interpretation of Frank H. Knight.<sup>2</sup> This "law" is represented in general by a three-dimensional surface, a "hill of returns,"<sup>3</sup> symmetrical with respect to two inputs. If input  $a$  is held constant and small portions of input  $b$  are successively combined with it, marginal returns to the variable input will at first increase and then eventually decrease. The same result will follow if  $a$  is made the variable input and  $b$  the fixed one.

The simplest functions that fulfill the "Knightian case" are of the following type:

$$(1) \quad x = (-Aa^3 + Ba^2b + Cab^2 - Dd^3)^{1/3}$$

or

$$(2) \quad x = \frac{-Aa^3 + Ba^2b + Cab^2 - Dd^3}{Ea^3 + Fb^3}$$

where  $x$  is output;  $a$  and  $b$  are inputs of different productive services; and  $A, B, C, D, E$ , and  $F$  are parameters such that  $B+C > A+D$ .

In the special case of

$$(2a) \quad x = \frac{-a^3 + 6a^2b + 6ab^2 - b^3}{a^3 + b^3}$$

we have

$$(2a') \quad \frac{\partial x}{\partial a} = \frac{-a^4 - 9a^2b^2 + 14ab^3 + 6b^4}{(a^3 + b^3)^2}$$

$$(2a'') \quad \frac{\partial^2 x}{\partial a^2} = \frac{14(a^3b^2 - 3a^2b^3 - 3ab^4 + b^5)}{(a^3 + b^3)^3}.$$

If  $b=1$ ,  $(2a'')$  is positive for  $a < 0.25$ . The partial derivatives for  $b$  are analogous.

<sup>1</sup> See, for instance, Erich Schneider [9, p. 197, n. 2].

<sup>2</sup> Compare Knight [6, pp. 99-100]; Cassels [2, pp. 223-36; reprint pp. 103-18, esp. p. 109].

<sup>3</sup> Compare Edgeworth [3, p. 75], Fisher [4, pp. 304-11], and Carlson [1, p. 18].

There are now two crucial points in these functions. For  $b$  a constant,  $x$  will be negative for  $a=0$  and will become positive for  $a>q>0$ , where  $q$  is some positive value of  $a$ . That is, these symmetrical functions all contradict the usual graphical representation in textbooks, where the total product curve (as a function of one variable input) begins in the origin of coordinates. The same contradiction holds for functions like

$$(3) \quad x = \frac{(-Aa^3b + Ba^2b^2 - Cab^3)}{Ea^3 + Fb^3}$$

because the economically relevant region with positive marginal returns begins where the variable input is greater than zero.

It is perhaps even more interesting to compare the Knightian case of the law of diminishing returns with the original agricultural examples, especially with those of Turgot [10, p. 420] and Wicksell [11, pp. 354-55]. These examples imply a positive output even when no variable input (for instance, manure) is used. For this condition to hold, production function (2) must (for instance) be rewritten as

$$(4) \quad x = \frac{-Aa^3 + Ba^2b + Cab^2 + Db^3}{Ea^2 + Fb^2}.$$

In such a case, the isoquants trace out a rather odd pattern. In the normal Knightian case neither one of the two inputs can be entirely dispensed with if output is to be positive, even in the long run when both inputs are variable. In the economic region of substitution all isoquants obey the principle of diminishing marginal rate of substitution.<sup>4</sup> This is not so in the Turgot-Wicksell case. Here one input [ $a$  in (4)] can be entirely eliminated without eliminating output, and for small quantities of this input  $a$  there is an increasing marginal rate of substitution of  $b$  for  $a$ . The isoquants in the Turgot-Wicksell case are concave toward the origin for small values of  $a$  and convex only for larger values of  $a$ . This can be seen when we define the marginal rate of substitution of  $b$  for  $a$  as

$$r_b = \frac{-\partial x}{\partial a} \bigg/ \frac{\partial x}{\partial b}.$$

In the Knightian case (2a)

$$(5) \quad r_b = - \left( \frac{-a^4 - 9a^2b^2 + 14ab^3 + 6b^4}{6a^4 + 14a^2b - 9a^2b^2 - b^4} \right).$$

In the Turgot-Wicksell case [(4) with the same parameters as (2a)]

$$(6) \quad r_b = - \left( \frac{-a^4 - 9a^2b^2 + 10ab^3 + 6b^4}{6a^4 + 14a^2b - 3a^2b^2 + b^4} \right).$$

Both (5) and (6) may be reduced to functions of the ratio  $a/b$ , and the described properties may then be easily verified.

As is well known, the fact that neither input is dispensable—that is,

<sup>4</sup> See Hicks [5, p. 20].

the fact that isoquants are of the normal Cassels-type [2, p. 109]—does not imply marginal returns that first increase and then decrease. We can see this from the production function

$$(7) \quad x = (-Aa^2 + 2Bab - Cb^2)^{1/2}, \quad \text{for } B^2 > AC,$$

which implies isoquants of the Cassels-type but which displays diminishing returns from the beginning. It follows that the traditional law of diminishing returns is not implied by the dual conditions of (1) indispensability of both inputs and (2) a fixed ("indivisible") amount of one of them. Moreover, these dual conditions are not met by the famous historical examples of Turgot and Wicksell, both of which imply dispensability of one input. These historical examples contradict the general principle of a diminishing marginal rate of substitution. The properties of inputs are different in the two cases, those of Knight and Turgot-Wicksell.

As far as I can see, this dichotomy has never been mentioned in our textbooks. I think the failure to do so has resulted from the loose practice of not basing productivity curves and isoquants on specified algebraic production functions.

### Diminshing Returns and Linear Homogeneity: Comment

Professor Nutter should be commended for showing, figures in hand, that the same production function can exhibit constant returns to scale *and* increasing (diminishing) returns to one factor of production. This is a point which economics students often fail to grasp. In the process, however, he may have raised fresh doubts in the minds of our charges on the relationship between the marginal products of the variable and fixed factors.

Using the linear and homogeneous function

$$x = 22a^{1/4}b^{3/4} - 20a^{1/3}b^{2/3}$$

where  $x$  is output and  $a$  and  $b$  are the two inputs, Nutter shows that the marginal product of  $b$  increases over the range  $2.45 > b > 1$ , and concludes:

Of course, over the range at which  $b$  has increasing returns,  $a$  has a negative marginal product. That is,

$$\frac{\partial x}{\partial a} < 0 \quad \text{for } 1 < b/a < 2.45.$$

The essential point is that the condition of linear homogeneity in a production function does not, in and of itself, rule out areas of short-run increasing returns (negative marginal products) to some inputs.

This may easily mislead the reader into thinking that increasing returns (in the conventional sense of "increasing *marginal* returns") to one input imply a negative marginal product for the other input. Now this is not necessarily so. The correct statement is that increasing *average* returns to the variable factor imply a negative marginal product for the fixed factor, and conversely (for a proof, see George Stigler, *The Theory of Price*, New York 1952, rev. ed., p. 302, mathematical note 9).

Using Nutter's production function, it can be seen that  $\partial x/\partial a$  is negative over a wider range than the one indicated, i.e.,

$$\frac{\partial x}{\partial a} < 0 \quad \text{for } 1 < b/a < 10.06$$

as the average product of  $b$ , with  $a=1$ , reaches its maximum for  $b=10.06$ .

### Diminishing Returns and Linear Homogeneity: Reply

My one-page note on increasing returns and linear homogeneity has borne unexpected returns of its own, some positive and some negative. In stimulating the communications of Dr. Dieter Schneider, Mr. de Fontenay, Professor John Rowe, and Professor Ryazo Sato, it has justified itself and hence needs no further defense. Were it not for the nature of Professor Liebhafsky's response, I would remain silent, but under the circumstances I feel I must make a few remarks.

My note deals simply with a simple issue unquestionably raised in Liebhafsky's book (*The Nature of Price Theory*, Homewood, Ill. 1963, p. 126) as well as in other texts. That issue has to do with whether it is possible to specify a linear and homogeneous production function in which marginal returns to a variable input first increase and then decrease as the variable input increases, other inputs fixed. The note was designed to meet that straightforward issue alone and not to be a rigorous discourse on the properties of prototype production functions, already well known to practicing economists, or on anything else. Reacting with puzzling vehemence, Liebhafsky now denies that he raised the issue in the first place, criticizes me for not discussing something else, and finds fault with my arithmetic. The last point is valid.

What he did or did not say is no doubt more important to Liebhafsky than to others, and there is therefore no point in dragging out a fruitless exegetical controversy. It is sufficient for me to say that he has not persuaded me that my original interpretation of his position was wrong. The footnote (*ibid.*) that I quoted speaks for itself, and it is not modified in any significant way by the surrounding text (*ibid.*, pp. 123-26). Moreover, the later statement (*ibid.*, p. 133) now cited by Liebhafsky does not alter the central issue. It merely says that marginal returns can *either* increase *or* decrease as the variable input increases, not that they can do both. Otherwise, what is the point of the earlier footnote? Finally, Liebhafsky's present insistence on linking the question of a maximum point in the short-run total product curve with the question of an inflection point is clearly an afterthought, since the two are not linked together in the cited footnote or the immediately surrounding discussion in his book. It is relevant to observe that he does not refer to diagrams of Stigler, Leftwich, or any other particular economist in his book even though he now does in his comment on my note.

But enough of such extraneous matters. Liebhafsky does offer two more relevant criticisms. First, he points out an arithmetic error on my part. (I ignore the typographical slip that set  $4/3$  as  $3/4$ .) My statement that "if  $\alpha=1$ , equations (1) and (2) are positive for all  $b>0.998$ " should read "are both positive for all  $b>0.319$ ." This mistake, an unfortunate and inexcusable copying error on my part, does not affect the general argument.

Liebhafsky, along with Mr. de Fontenay, also takes me to task for a careless statement about the relation between increasing marginal returns to one input and negative returns to the other. My statement, inserted as an afterthought to satisfy a referee, happens to be correct as it stands (except for the arithmetical mistake noted above), but it is misleading and incomplete. Because of some interesting points made by Dr. Schneider, it will therefore be useful to set forth more rigorously some of the relations that can exist in a linear and homogeneous production function among the various average and marginal product curves, and what those relations imply about the shape of isoquants.

The following relevant conditions hold for a linear and homogeneous production function  $\phi(a, b)$ :

- (1)  $\phi_a = x/a - (b/a)\phi_b$
- (2)  $\phi_{aa} = (b/a)^2\phi_{bb} = - (b/a)\phi_{ab}$
- (3)  $\partial b/\partial a = - \phi_a/\phi_b$
- (4)  $\partial^2 b/\partial a^2 = - (x/b)^2\phi_{aa}/\phi_b^3$

For convenience in later discussion of Schneider's contribution, let us refer to  $a$  as the variable input in the short run and to  $b$  as the fixed input.

As Liebhafsky and De Fontenay point out, we see from (1) that the marginal product of  $b$  will be negative if, and only if, the marginal product of  $a$  is larger than the average product of  $a$ —that is, if, and only if, the average product of  $a$  increases with  $a/b$ . Of course, an increasing average product of  $a$  does not imply an increasing marginal product of  $a$ . Similarly, an increasing marginal product of  $a$  does not imply a marginal product of  $a$  larger than the average product of  $a$ .

The marginal products of  $a$  and  $b$  cannot both be negative at any given  $a/b$  within the relevant region of the production function, which is to say that the average product can be increasing for only one input. It therefore follows from (3) that isoquants will be downward sloping at a given  $a/b$  if, and only if, the marginal products of both inputs are positive or, put another way, the average products of both inputs are diminishing. Isoquants will be upward-sloping if, and only if, the marginal product of one input is negative, which is to say that the average product of the other input is increasing.

Finally, we see from (4) and the preceding argument that isoquants will be convex toward the  $a$ -axis at a given  $a/b$  if, and only if, the marginal and average products of  $a$  are moving in the same direction. The isoquants will be concave if, and only if, the average and marginal products of  $a$  are moving in opposite directions.

In the case of a symmetrical production function with Knightian properties as represented by, for example, Schneider's function (2), isoquants will look like hairpins and will pass through five stages in their shapes as  $a/b$  increases through its relevant range. In stage one, isoquants will be upward-sloping and convex toward the  $a$ -axis; in stage two, upward-

sloping and concave; in stage three, downward-sloping and convex; in stage four, upward-sloping and convex; and in stage five, upward-sloping and concave. These correspond, of course, to the five stages in the Knightian law of variable proportions.

In the Turgot-Wicksell case as represented by Schneider's asymmetrical function (4), the first three stages of the Knightian case are replaced by two stages in which isoquants are downward-sloping, first concave and then convex to the  $a$ -axis. This comes about because the average product of  $a$  diminishes from the start—a finite output is possible without use of any  $a$ —even though the marginal product of  $a$  first increases and then diminishes. Thus the increasing returns to  $a$  in the Turgot-Wicksell case are strictly marginal and not average.

I will conclude with a comment on Schneider's statement that textbooks usually show the total product curve as starting at the origin, while his symmetrical function makes it start at some positive value for the variable input. Whatever may be the case for usual textbooks, Schneider's symmetrical function corresponds entirely with Knight's original formulation (*Risk, Uncertainty, and Profit*, London School Reprints of Scarce Works, 1957, pp. 99–100), which sets the total product at zero when the variable input is below a critically small level.

For this reason, Schneider's equation (1) or (2) is to be preferred to Rowe's function (3) or Sato's equation (1), since they imply a short-run total product curve that begins in the origin and becomes asymptotic to the horizontal axis. A generalized expression for a linear and homogeneous production function with all the Knightian properties would apparently be

$$(5) \quad x = \left( -\beta_0 a^{m/n} + \sum_{i=1}^{m-1} \beta_i a^{(m-i)/n} b^{i/n} - \beta_m b^{m/n} \right)^{n/m}$$

or

$$(6) \quad x = \left( -\beta_0 a^{m/n} + \sum_{i=1}^{m-1} \beta_i a^{(m-i)/n} b^{i/n} - \beta_m b^{m/n} \right) \cdot (\alpha_0 a^{(m-n)/n} + \alpha_1 b^{(m-n)/n})^{-1}$$

where  $x$  is output,  $a$  and  $b$  are inputs,  $\alpha$ 's and  $\beta$ 's are positive constants such that

$$\sum_{i=1}^{m-1} \beta_i > \beta_0 + \beta_m,$$

and  $m$  and  $n$  are any two different odd integers.

### Multilateral Balancing in International Trade: Comment

In a recent article in this *Review* [2] Michael Michaely has introduced a new index of multilateral balancing of trade. At the same time he has formulated another such index based on an early report published by the League of Nations [1, p. 60].<sup>1</sup> He has then proceeded to use his own index rather than the League's (or more accurately, the one based on the League's report) for calculating the indices of multilateral balancing for various countries. Surprisingly, Michaely nowhere discusses why he has used his own index rather than the League's or any other index. He has done so presumably because he considers his index in some way superior to others. This can be the only justification one can give for introducing a new index when an old one is known to exist. The purpose of this note is to examine the validity of this implicit claim on behalf of Michaely's index.

Before we do that, however, we shall have to remove a slip in Michaely's algebraic formulation of the League's index. The League's report divides total trade into three parts: bilaterally balanced ( $BB$ ), multilaterally balanced ( $MB$ ), and unbalanced ( $U$ ). While in his footnote 7 [2, p. 693] Michaely interprets the League's index to mean  $MB/(BB+MB)$ , in his footnote 5 [2, pp. 688-89], where he gives the algebraic formulation of the index, he declares it wrongly to be  $(MB+U)/(BB+MB)$ .

Using a simplified version of Michaely's notations (which will be employed in the rest of this note), if we let  $X$  and  $M$ , respectively, stand for the total export and import of the country concerned, and  $X_i$  and  $M_i$  for its export to and import from country  $i$ , then the League's index (following Michaely's interpretation) would be

$$T_L = \frac{\sum_{i=1}^n |X_i - M_i| - |X - M|}{X + M - |X - M|}$$

where  $n$  is the number of the trading partners of the country concerned, and not

$$T_L' = \frac{\sum_{i=1}^n |X_i - M_i|}{X + M - |X - M|}$$

as in Michaely's algebraic formulation [2, pp. 688-89].

One obvious difference between the two formulae is that while the former ( $T_L$ ) has a range of values between zero and one, the latter ( $T_L'$ ) has no maximum limit. Thus only  $T_L$  can be expressed in percentage terms.

Michaely's own index (without multiplying it by 100), expressed in the above symbols,

$$T_M = \frac{\sum_{i=1}^n \left| \frac{X_i}{X} - \frac{M_i}{M} \right|}{2}$$

<sup>1</sup> As cited by Michaely in [2].

also possesses the characteristic of varying between zero and one. This no doubt is a desirable characteristic, but in this respect Michaely's index is not superior to the correctly formulated League's index.

But this is not all. There is at least one practical and one theoretical reason for preferring the reformulated League's index (henceforth called simply "League's index"). The practical reason is simply that it is very much easier to calculate. When calculating the League's index for a particular country, only one operation of division is required, while two such operations are needed for each trading partner of the country when Michaely's index is calculated. Thus if a country has 70 trading partners, Michaely's index would require 140 division operations, some of them showing quotients only in the sixth or seventh decimal place, against only one such operation for the League's index.

However, the much more serious deficiency of Michaely's index is analytical. There is nothing in his formula to remove or even reduce the influence of unbalanced trade. Michaely is himself aware of this and has therefore excluded a number of countries from consideration because they had a large trade imbalance. He even suggests that the higher average of the indices for various countries in 1948 as compared with 1938 may be the result of a greater unbalanced trade in 1948, rather than of greater multilateral trading in that year [2, pp. 689-91]. A simple illustration in Table I below shows clearly how Michaely's neglect of unbalanced trade may lead to absurd results.

Suppose that there are only three countries, A, B, and C, and A's trade with the other two is as follows:

TABLE 1  
(Value in million dollars)

	Export to	Import from
Country B	50	50
Country C	50	100

Here country A has no trade surplus with either of the two countries. Therefore, confining our attention to the above situation, there is no possibility of any multilateral settlement. But by using Michaely's formula ( $T_M$ ) we should get 0.167 as the index of multilateral balancing. The conclusion is obvious that a nonzero value of Michaely's index is no guarantee at all that the situation calls for a multilateral balancing of trade.

If we now turn to the League's index ( $T_L$ ), we can immediately see the attempt to remove the influence of unbalanced trade in the last term of both the numerator and the denominator. One result of this procedure is that we can be sure of obtaining zero value of the index where no multilateral settlement of trade is possible—it is in fact the result of taking away the unbalanced trade from the numerator only. Thus if we apply the League's index to the situation illustrated in Table I, we shall get a zero value for the index, which is as it should be.

The case for the League's index would appear even stronger when we realize that Michaely's and the League's indices become identical when the

trade is balanced, as in this case  $X$  equals  $M$  and both the formulae reduce to:

$$\frac{\sum_{i=1}^n |X_i - M_i|}{2X}.$$

The difference between the two, therefore, exists only when trade is unbalanced, in which case the League's index is demonstrably a superior one. Incidentally, in all cases of unbalanced trade the League's index gives a lower value than Michaely's.

Finally we may mention another index which is similar to that of the League, but which is slightly simpler in concept as well as in calculation. This index has been used, among many others, by Erik Thorbecke [3, p. 82].<sup>2</sup> This is the multilaterally balanced trade expressed as a proportion of total trade. In the above symbols it can be expressed as:

$$T_T = \frac{\sum_{i=1}^n |X_i - M_i| - |X - M|}{X + M}.$$

This also gives the same value of the index as the League's and Michaely's when trade is balanced. In all other cases it gives a lower value than the League's, which, as we have noted, gives a lower value than Michaely's.  $T_T$  also lies between zero and one, and, like the League's index, would give a zero value for the illustration in Table I. The last characteristic of  $T_T$  results from taking away the unbalanced trade from the numerator. But since the unbalanced trade has not been subtracted from the denominator (as was done in the case of  $T_L$ ), an increase in unbalanced trade would lower the value of the index.

Comparing the three indices we find that both the League's index and Thorbecke's index give the correct answer to the problem set in Table I, but that Michaely's index does not do so. Hence both  $T_L$  and  $T_T$  appear superior to  $T_M$ . Between  $T_L$  and  $T_T$ , my own preference is for  $T_L$ , mainly because of its neutral behavior in the face of a change in unbalanced trade. While an increase in unbalanced trade raises the value of Michaely's index, it lowers the value of Thorbecke's index. Only the League's index remains unaffected. In the case where there is no unbalanced trade (which of course would probably never be found in practice), we have already seen that there is no difference among the three.

### Multilateral Balancing in International Trade: Reply

In his comment on my measurement of multilateral balancing in international trade [1], Professor Syed Ahmad (1) removes a slip in my algebraic formulation of the League of Nations' index of multilateral balancing—a task for which I am grateful; and (2) argues that the League of Nations' index should be preferred to the one used by me—an argument which I should like to dispute.<sup>1</sup>

Although Ahmad claims a general superiority of the League's index, his discussion is limited to a particular case, which seems to him to be clear-cut. In making explicit the underlying difference between the two indexes, it may indeed be most convenient to refer to this case. I shall also follow, for illustration, the numerical example provided by Ahmad. Country A's trade looks, then, as follows:

	<i>A's Exports to:</i>	<i>A's Imports from:</i>
Country B	50	50
Country C	50	100
	<hr/>	<hr/>
World	100	150

This is a situation in which country A has an over-all import surplus and no export surplus to any of its trading partners. Under these circumstances, Ahmad argues, "there is no possibility of any multilateral settlement." And any index, such as my own, which would provide here a positive coefficient of multilateral balancing, would therefore "lead to absurd results." But is this really so?

Country A, in this example, has an over-all import surplus of 50 units. It finances 50 units of imports of goods (and services) through capital imports; that is, it exchanges 50 units of financial assets for an equal value of goods. This exchange may be bilateral, or it may be multilateral. A broad definition of an index of multilateral balancing would have to take this exchange into account. I have chosen, on the other hand, to define the meas-

<sup>1</sup> I shall confine myself to a discussion of the conceptual meaning of the indexes. The practical reason which Ahmad suggests for preferring the League's index to mine, namely, that my index requires more operations of division than the League's, must be of minor importance—as Ahmad seems to agree. Incidentally, for the interwar years it would work the other way: the trade figures released by the League itself, in its annuals of *International Trade Statistics*, appeared as percentages of total exports or imports, respectively.

urement of multilateral balancing in a more narrow sense, so that it excludes the exchange of goods for financial assets. This has been done for several reasons,<sup>2</sup> whose acceptance is implied, it seems to me, in the League's index, and which are not disputed by Ahmad.

There is thus need to eliminate somehow that part of imports which is financed by capital imports, and treat the trade of the country in question as if it were balanced. There may be various ways of doing it, and each of them rests on arbitrary assumptions.

The question may be stated as follows: what would have happened to country A's trade had capital imports disappeared and the country's trade been balanced? The use of the League's index assumes, in the situation on hand, that the elimination of 50 units of capital imports would have reduced imports *from country C*—the one with whom country A maintains an import surplus—by the same amount. This, however, is only one of many possibilities. Even had the capital imports been provided in fact by country C, there is no need that their elimination would have expressed itself necessarily in the reduction of imports from C. Moreover, without access to further data, there is no reason to presume that country C is indeed the source of capital imports—it could be country B just as well.

In other words, the use of the League's index assumes, implicitly, that all exchanges of goods for financial assets are necessarily bilateral. This, obviously, is merely one of various possible assumptions. One might, for instance, go to the other extreme and adopt the assumption that all such exchanges are multilateral. I cannot see any a priori reason for selecting either of these two extremes. The use of my index amounts to the "neutral" assumption that, in the absence of capital imports, A's imports from each country would decline *in the same proportion*.<sup>3</sup> A's trade would then be as follows:<sup>4</sup>

	<i>A's Exports to:</i>	<i>A's Imports from:</i>
Country B	50	33
Country C	50	67
	<hr/>	<hr/>
World	100	100

<sup>2</sup> See the discussion in [1, pp. 686-88].

<sup>3</sup> The index of multilateral balancing is, then, (using Ahmad's notation)

$$\frac{\sum_i \left| Xi - Mi \frac{X}{M} \right|}{X + M - (M - X)}$$

This may easily be shown to be equal to the index used by me, which is

$$\frac{\sum_i \left| \frac{Xi}{X} - \frac{Mi}{M} \right|}{2}$$

<sup>4</sup> One might assume a proportionate increase of exports instead of a reduction of imports. The result, for the purpose on hand, would obviously be the same. Likewise, the argument would be similar—with proper qualifications—for a country running an export surplus rather than an import surplus.

Here, of course, part of country A's trade is multilaterally balanced—hence the positive value of my index of multilateral balancing.

Stated alternatively, the use of my index assumes that the exchanges of goods for financial assets are multilateral to the same extent as are the exchanges of goods for other goods. While, to repeat, this is nothing but an arbitrary assumption, it seems to me to be preferable, in the absence of any contradicting information or indication, to the one implied in the League's index.<sup>5</sup>

To sum up: It is obviously incorrect—as, I hope, I have shown here—that “there is nothing in [Michael's] formula to remove or even reduce the influence of unbalanced trade.” Both the League's formula and my own do try to remove this influence; they do it by asking, implicitly, what would the country's trade look like in the absence of capital imports? In answering this question the two indexes differ in resorting to different assumptions. I believe I have selected the better assumption; but this may be a reflection of one's feeling that whenever arbitrariness is concerned, his is preferable to anybody else's.<sup>6</sup>

<sup>5</sup> I cannot quite see the rationale of the index which Ahmad designates as Thorbecke's (Thorbecke himself, as would appear from [2, p. 81], probably has in mind something like the League's index, rather than this one). This index does not, incidentally, have the property of ranging from zero to one. Its lower limit is indeed zero; but its upper limit, as may easily be verified, is below one in a country with unbalanced trade.

<sup>6</sup> It may be possible to devise tests which would provide a more objective yardstick for the selection of the proper assumption. It may be rewarding, for instance—although I have not carried it out—to run a multiple correlation in which the degree of imbalance in the country's trade would be added to the factors which are presumed to genuinely affect the degree of multilateral balancing in the country's trade. This may be repeated for each of the alternative concepts of the index of multilateral balancing. The lower the correlation found between unbalanced trade and multilateral balancing, the stronger should be our belief that the index of multilateral balancing is free of bias introduced by the existence of capital imports or exports.

#### Note on Lag in Effect of Monetary Policy

Because of the long lag in the publication of the research studies prepared for the Commission on Money and Credit, many readers are likely to be misled about the present state of some issues discussed. This note is to call their attention to one such issue, namely, a criticism of my work to which I replied in print some two years before the publication of the criticism.

In their article on “Lags in Fiscal and Monetary Policy,” which appears

in the CMC volume entitled *Stabilization Policies*, Albert Ando, E. Cary Brown, Robert M. Solow, and John Kareken state [2, p. 3]:

We have come to the conclusion . . . that this proposition [Milton Friedman's proposition that the effects of monetary policy actions on aggregate output are powerful, but occur with a very long and highly variable lag] simply will not hold water. We believe that the method underlying the proposition is based on a *non sequitur*, and further we have convincing evidence that all or most of the Friedman lag is a statistical artifact.<sup>1</sup>

Though this article first appeared in published form in December, 1963, a mimeographed version was available in 1960. And near-identical criticisms were made in an article by John Culbertson. I replied to both in an article [1] on "The Lag in the Effect of Monetary Policy," published in October, 1961.

It is amusing that, while the authors assert that "when correction is made for the bias" which is said to be inherent in what is termed the "Friedman approach," "no systematic lag appears," they themselves conclude, using other techniques, "that some substantial stabilizing power results after a lapse of time of the order of six to nine months"—a conclusion that, to put it mildly, is in no way inconsistent with my own. I find it even more amusing that, with appropriate changes, we also agree on another point: we each believe the other has come to approximately correct conclusions by faulty methods!

The main tool Kareken and Solow use is multiple regression in which prior values of the dependent variable enter as independent variables along with the current value of the variable suspected of having a lagged effect (call this the operational variable). The coefficients of the prior values of the dependent variable are used to estimate the distributed lag effect of the operational variable. This procedure will, under appropriate conditions, yield a valid estimate of the distributed lag, *if such a lag exists*. But, by itself, it does not provide any evidence on the existence of the lag, since it cannot discriminate between serial correlation in the dependent variable which arises from other sources (e.g., errors of measurement) and that which arises from the distributed lag effect of the operational variable. When other sources do make for serial correlation, the Kareken-Solow method is likely to produce poor and biased estimates of whatever distributed lag does exist—at least, that has been my experience in some calculations of this kind I have made. Perhaps this difficulty does not affect the Solow-Kareken calculations, but they give no evidence whatsoever on this point, and as yet, I believe, we have too little experience with the use of the technique to be able to accept its results as reliable without other confirming evidence.

## The Paternity of an Index

In the March issue of this *Review*, Benton F. Massell [5, pp. 52 ff.] uses an index of trade concentration of the form  $\sqrt{\sum (x_i/x)^2}$  where  $x_i$  is the value of a country's trade in commodity  $i$  (or with trading partner  $i$ ) in some period, while  $x$  is the country's total trade. This index appears to have come into wide use recently and, to my rather chagrined surprise, is referred to, by Massell as well as by Kindleberger [4, p. 143], Michaely [6], and Tinbergen [9, pp. 268 ff.], as the "Gini index" or "Gini coefficient."<sup>1</sup> Given the sudden popularity of the measure, I feel that I should stand up for my rights as its originator. It was first introduced and computed for a large number of countries in my book *National Power and the Structure of Foreign Trade* [3, Ch. 7 and pp. 157-62]. As explained there, the use of the index is indicated when concentration is a function of both unequal distribution and fewness. The traditional measures of concentration, generally devised in connection with income distribution and the Lorenz curve, are sensitive only to inequality of distribution, and we do owe several such measures to Gini.

The confusion on this score is the stranger as I referred at length in my book to the important work of the Italian statisticians on measurement of concentration, and particularly to Gini [3, pp. 157-58]. Upon devising the index I went carefully through the relevant literature because I strongly suspected that so simple a measure might already have occurred to someone. But no prior inventor was to be found.

To complicate the story, I must add that there was a posterior inventor, O. C. Herfindahl [2], who in 1950 proposed the same index, except for the square root. While obviously unaware of my earlier work when writing, Herfindahl did acknowledge it in a footnote [2, Ch. 1 and p. 21, n.]. Nevertheless, when the index is used for measuring industrial concentration, the second principal area of its application, it is now usually referred to as the "Herfindahl index," owing to a well-known paper by Rosenbluth [7] who has, however, recently made a valiant, but probably vain, attempt to straighten the matter out [8, pp. 391-92].

The net result is that my index is named either after Gini who did not invent it at all or after Herfindahl who reinvented it. Well, it's a cruel world.

### The Opportunity Locus in a Hedging Decision: A Correction

In my 1961 *AER* article on spot and futures prices,<sup>1</sup> I drew the opportunity locus between expected return ( $E$ ) and risk ( $R$ ) as a straight line. This is incorrect; it should be a concave function (negative second derivative). All the other results of that paper are unchanged.

The risk on a linear combination of hedged and unhedged stock is equation (1), where  $x$  refers to the fraction unhedged.

$$(1) \quad R = \text{var} [xu + (1 - x)h].$$

Variables  $u$  and  $h$  are the returns derived from unhedged and hedged stock, respectively.

(a)  $u = p^* - p - m$  where  $p^*$  is the expected price,  $p$  is the current price, and  $m$  is the marginal net carrying costs.

(b)  $h = (p^* - p) - (q^* - q) - m$  where  $q$  is the futures price, and  $q^*$  is the expected futures price at the time the contract will be liquidated.

Solving for  $R$ , we obtain equation (2).  $\sigma_p^2$  is the variance of  $p^*$ ;  $\sigma_q^2$  is the variance of  $q^*$ , and  $r$  is the correlation coefficient between  $p^*$  and  $q^*$ .

$$R(x) = \sigma_p^2 + (1 - x)^2 \sigma_q^2 - 2r(1 - x)\sigma_p\sigma_q.$$

$$(2) \quad \begin{aligned} (a) \quad R(0) &= \sigma_p^2 + \sigma_q^2 - 2r\sigma_p\sigma_q \\ (b) \quad R(1) &= \sigma_p^2 \end{aligned}$$

<sup>1</sup> J. L. Stein, "The Simultaneous Determination of Spot and Futures Prices," *Am. Econ. Rev.*, Dec. 1961, 51, 1012-25.

The slope of the opportunity locus is  $dE/dR$ , where  $E = xu + (1-x)h$ , and is equation (3).

$$\begin{aligned} \frac{dE}{dR} &= \frac{dE/dx}{dR/dx} = \frac{(u-h)/2}{(r\sigma_p\sigma_q - \sigma_q^2) + x\sigma_q^2} = f(x). \\ (3) \quad (a) \quad f(0) &= \frac{(u-h)/2}{r\sigma_p\sigma_q - \sigma_q^2}, \\ (b) \quad f(1) &= \frac{(u-h)/2}{r\sigma_p\sigma_q}. \end{aligned}$$

The slope of the opportunity locus is positive at  $x=1$  if the expected return on unhedged stock exceeds that on hedged stock. When  $x=0$ , the slope will be negative if the variance of  $q^*$  exceeds that of  $p^*$ . There would exist an  $x$  between zero and unity where a vertical tangent occurs.

Since  $f'(x)$  is negative, the general concavity is proved.

No change is required in the rest of the paper.

### General Economics; Methodology

*Bargaining Behavior.* By LAWRENCE E. FOURAKER AND SIDNEY SIEGEL.  
New York: McGraw-Hill Book Co., 1963. Pp. ix, 309. \$8.95.

The purpose of this book is to examine the decision-making behavior of human beings when confronted with a conflict situation in which there are both competitive and cooperative elements. From the social sciences, economics was chosen as a suitable vehicle for this study because of its quantitative nature and its large body of theory. The study is divided into three parts: bilateral monopoly with equal strength, bilateral monopoly with unequal strength, and oligopoly. The results of the equal-strength case were reported earlier in "Bargaining and Group Decision Making" by the same authors (1960), and this book is concerned with the latter two categories.

The unequal-strength bilateral monopoly case consists of a single buyer and seller attempting to decide on the price and quantity of goods to be sold. This situation is simulated when the subjects in the experiment attempt, by examining tables relating the profit to be made with the prices and quantities sold, to maximize their profits (which they are subsequently allowed to keep). In this model the seller fixes the quantities to be sold and the buyer names the price. According to the hypothesis one of two types of resultant profit-splitting should occur. Either the payoff should be Pareto optimal, i.e., it should be impossible for the two participants simultaneously to improve their profits; or a Bowley solution should occur, i.e., the seller should set that price which will maximize his profits, assuming the buyer subsequently sets the quantities so as to maximize his own profits. In general, the Bowley solution will not be Pareto optimal.

There were three independent variables considered by the experimenters. The first was the amount of information available to the subjects. The subjects either had complete information: knowledge about the profits to himself and his partner as the result of any contract; or incomplete information: knowledge of only his own profit. The second variable was the method of bargaining. Bargaining was either a single transaction whereby the seller offered a price, the buyer a quantity, and the bargaining was over, or there was a sequence of price and quantity proposals culminating in an agreement. Finally, because it was felt that there might be a tendency toward the culturally favored point where the profits are split evenly, the position of this point (whether in the Pareto or Bowley solution) was also considered to be an independent variable.

It was predicted that complete information, repeated bidding, and the equal-profit point lying on the Pareto optimality-point set, would all tend to make the outcome Pareto optimal. The fact that the Bowley point has strong equilibrium properties and is essentially unilaterally enforceable while the

Pareto optimal result requires cooperation, communication, and information makes this hypothesis reasonable.

The set of experiments was undertaken at the University of Pennsylvania with 53 pairs of undergraduates as subjects. The subjects were never confronted with their counterparts, and all communications were made by written sheets of paper so that there was no visual or aural contact. It was recognized that there might be some effect of social interaction, and this was deliberately avoided. With three independent variables, where each may be in either of two states, there are eight possible combinations. It was felt that for the incomplete-information state only the case with repeated bidding where the equal-profit point was Pareto optimal was of interest so that only five cases were used.

Briefly, the results were as predicted. The most significant factor tending to put the outcome toward Pareto optimality was the form of bidding: repeated bargaining became a means of communication between the two players and, subsequently, a means of cooperation as well. Second in importance was the amount of information available; a knowledge of one's partner's profits, as well as one's own seemed to be necessary in reaching a Pareto optimal point. Finally the position of the equal-split point was least significant. The Bowley point, because of its strong equilibrium properties, predominated, however, except when the three favorable states of the three independent variables appeared in concert. The reasons for variations from the general tendencies mentioned above were also considered.

The last part of the study concerned itself with oligopoly: competition between a few competing sellers. Two types of situations were examined: in the first situation the sellers controlled only the single-variable quantity, in the second, only price. As a theoretical model for the first case the Cournot solution was considered. In this case it is assumed that only quantity may be adjusted and that the production of other firms is not influenced by the decision-maker's choice of production level. In the price-adjustment case the Bertrand solution was considered. It is thus assumed that the seller, in trying to maximize his profits, does not influence the already quoted price of his competitors.

There were three independent variables considered: the number of sellers (two and three were used), the amount of information given to the participants, and the "level of aspiration" of the participants. There were three categories for the latter variable—*rivalistic*, in which the participant attempts to maximize the difference between his own and his competitor's profits; *simple maximizer*, where he attempts to maximize his own profit; and *cooperative*, in which he places a positive value on his competitors' profits as well as his own. Although no attempt was made to categorize the players in advance, it was shown that players could recognize the Pareto optimal points and the competitive points as being the results of cooperative and rivalistic strategies when bonuses were given for cooperative and competitive behavior respectively.

As was predicted, incomplete information favors the Cournot and Bertrand solutions, the tendency toward the Bertrand solution becoming stronger, the

greater the dispersion, while the tendency in the Cournot case becomes greater as the number of players increases. Under complete information there is more dispersion in both cases, and the sources of this dispersion are discussed.

The results of this study as well as of the earlier work by the same authors, and any future work along the lines they suggest, will be of interest to psychologists, economists, game theorists, and behavioral scientists, in general, for they lay an empirical foundation upon which any meaningful theory of human behavior must lie.

*Economic Policy and War Potential.* By MAX E. FIESER. Washington: Public Affairs Press, 1964. Pp. vi, 136. \$4.50.

Dr. Fieser criticizes U.S. protective measures for defense industry. Still important, these measures have had large impacts upon the world economy during and since the Korean War. Yet he finds either little explicit economic analysis to provide a rationale for them or analysis based upon outmoded mobilization concepts. He briefly reappraises World War II concepts, rightly finding them inappropriate for unlimited nuclear war or for possible limited wars. Then, however, his subsequent discussion fits within the old mobilization categories: matériel requirements, industrial capacity, criteria of essentiality, and the role of import restrictions.

No more is claimed than (p. 58) a "general framework within which the analysis of industrial defense potential and essentiality can proceed," i.e., sensibly ordered economic criteria to guide policy studies. The vital empirical content must be supplied elsewhere via industry studies that measure the excess burden from particular protective measures in terms of specific alternatives. This book will contribute to their orientation; while, in questioning old defense rationale and noting less clumsy instruments than import restrictions, it should help to counter naïve policies. But the trained interindustry analyst who has also absorbed such older defense references as Klaus Knorr's *War Potential of Nations* and Charles Hitch and Roland McKean's *The Economics of Defense in the Nuclear Age* will find little that is novel.

Beyond Fieser's chosen area lies economic planning for recuperation after general war, industrial reconversion if there should be drastic shifts in peacetime arms spending, and enhanced efficiency in acquiring arms systems. An author's scope is his privilege, especially when nobody has dealt adequately with such formidable topics. But can his proper cautions against excessive damage to international trade for outmoded defense reasons not be extended further? Is deliberately heightened interdependence now reasonable in some cases? If the United States neither needs nor can rely upon a huge mobilization after any hostilities start, we might look to greater dependence upon for-

eign sources, either because they are cheaper or less likely to be damaged. Fieser's analysis might be extended more positively, if more riskily.

*The Mythmakers—An Essay on Power and Wealth.* By B. D. NOSSITER. Boston: Houghton Mifflin, 1964. Pp. ix, 244. \$4.00.

This is an important book which should be read by all economists. B. D. Nossiter is a perceptive observer of economics as well as a penetrating critic of economists. He demonstrates great insight into economic problems, especially the problem of economic power. He is critical of the Kennedy administration—indeed, all recent administrations—for failures in the area of economic concentration. In making what is actually, if not avowedly, an assessment of the late President's economic policies, Nossiter describes the anatomy and operation of the American political economy and prescribes some remedies for what he considers clear and present ills. The immediate questions for which Nossiter seeks answers are:

Could the business-oriented policies of the New Frontier master the problems confronting the economy? Will the corporate vision bring about full employment of men and resources, quicken the sluggish pace of economic growth and bring material abundance to the surprisingly large group outside the affluent society? Is the existing economic structure capable of solving these problems, as the President implied, or are some institutional changes necessary?

Throughout much of his analysis, it is clear enough that economists are included among the mythmakers in the book. He demonstrates that much of contemporary economic theory is irrelevant or useless in terms of solving real problems. Nossiter also is critical of the artificial division drawn between politics and economics, describing expertly how this conventional division obscures analysis of the real world.

The book consists essentially of eight provocative essays ranging from "The Corporate Vision and the New Frontier" to "The Myth of Countervailing Power" and "The Two Half-Truths of Disarmament." The concluding essay tackles the engaging issue of "Planning and Freedom," in which Nossiter advances a modest proposal for consideration.

The first two essays are devoted to the economic doctrines of the Kennedy administration because the problems it faced and the choice of solutions illuminate themes that recur throughout the book. Nossiter observes that the Business Advisory Council's triumph over Secretary of Commerce Hodges in the spring of 1961 provided an important clue to the character of the new administration. He argues that, of all the myths in the business literature, one of the most imaginative and furthest removed from reality is that portraying the late President as anti-business. The New Frontier's main thrust is evaluated as clearly in the conservative direction, copied in the main from Eisenhower's

earlier program. As an illustration, Nossiter uses the administration's concern with the balance-of-payments deficit, which he notes "ran in the grooves marked out by the most orthodox banking thought." Similarly, he observes that the celebrated trade bill of 1962 was a "masterful invocation of nineteenth century liberal economic thought," very little of which would "give sleepless nights to Adam Smith, David Ricardo, John Stuart Mill, or corporations and banks with interests abroad."

On the dramatic 1962 clash over steel prices, Nossiter, with careful documentation, shows that the real issue was not Blough's deliberate personal challenge to the President, but the threat steel's action posed for the administration's wage-price policy, an essentially pro-business, conservative position. The President's acquiescence in the 1963 round of "selective" increases Nossiter regards as symptomatic of the administration's unwillingness or inability to confirm the 1962 victory with some new institutional arrangements to deal with corporate pricing power.

In brief, in every important area of economic policy—wage policy, tax policy, international trade and finance, federal spending—Nossiter reasons, it is doubtful that a Republican President could have done as much for "Wall Street" in his stereotype role as a "business tool."

His essay "The Visible Hands" is among the best. In contemporary versions of the fable of the invisible hand, the real and the spurious are "buried under layers of conventional belief and self-serving myth." Whereas the untutored observer takes for granted the overriding fact of economic concentration, says Nossiter, the distressing fact is that it is often ignored by economists and taken into account by government policy-makers only with reluctance and when it intrudes on their vision with a prominence that can't be denied. It is difficult to rebut his judgment that:

Then, too, economists have invested considerable intellectual capital in exploring a model world of small, competing firms. If adequate account was taken of the fact the industries are generally organized by a few competitors, much of this capital stock would become obsolete.

Nossiter recognizes that there are no panaceas or simple solutions to the problem of concentrated economic power, but he is disturbed that concentration and its consequences rank so near the bottom of the public and scholarly agenda. He is willing to accept the social conscience of the new breed of professional managers, but if indeed a world of abundance is close at hand in a world of concentration under neo-paternalism, he calls upon these socially responsible managers to lead us into it and cease the delay. Nossiter asks, how exactly do corporate managers determine when a decision is socially responsible? What are their standards and how are they derived? How are competing claims measured and weighed in the boardrooms? If backsliding occurs, what recourse does society have?

Countervailing power cannot act as a social and political check on the power of business—or that of labor and government. Nossiter cites the record of regulatory commissions in evaluating the balance theory or redressed power through government countervaleances. He finds symbiotic partnerships extend-

ing beyond the usual commissions to the cabinet departments as well. He concludes that in the present state of affairs the government is more likely to combine with than to offset business power.

Nossiter argues that our economy is hobbled by its economic structure. Despite the spread of affluence and near-affluence in our economy, there is an impressive amount of poverty and deprivation, compounded by a disturbing level of chronic unemployment. Our political-economic structure, built around corporate concentration, threatens to transform cures into placebos. Nossiter views this structure's potential for damage as acutely linked to a disarming economy. In one of the best of his essays, "The Two Half-Truths of Disarmament," he examines current illusions about the lurking fear that American prosperity depends on arms spending and that cutbacks would trigger a recession or depression. The heavy interlacing of military spending in the economy is viewed as a possible threat to economic stability. He argues that reliance on the post-World War II experience for a disarmament and demobilization parallel is deceptive. Following Emile Benoit, Nossiter sees a more subtle difficulty for our lagging growth rate arising from the fact that so much of our search for new knowledge is financed by arms spending. In net, however, Nossiter recognizes that arms reduction would pose new dilemmas which could be eased by programs of public expenditures and reduction in taxes.

Thus, instead of creating problems, Nossiter sees disarmament as offering enormous opportunities for real advances in material well-being. But if disarmament is to prove a blessing and not an economic curse, there must be advance planning for the transition. Plans for tax cuts, expansion of specific government undertakings, and other economic policies would serve two purposes: help calm those who fear disarmament and insure that appropriate measures to hurdle the transition itself will be taken.

The kind of planning envisaged by Nossiter is noncoercive, "indicative" planning of the European variety, a "systematic confrontation of ends with means." The new style of planning accepts the concentration of markets, dominated by a handful of firms, and strong labor unions, as conferring a host of possible advantages—technological and political—that flow from this order. Expanding upon Gardiner Means' recent proposals to control corporate action (*Pricing Power and the Public Interest*), Nossiter suggests we harness the energies of these great institutions through a diet more heavily laced with carrots than sticks. It would be planning by assent, whereby government economists would tentatively select a plausible rate of growth for the economy, from which a four-to-five-year model would be developed, spelling out the likely spending by the household, government, and industry sectors of our national income accounts. Each major industry, leading businessmen, union executives, and public representatives would calculate the model's implications for their specific area of interest. "The Plan" would emerge, following reconciliation of the projections of individual industries and elimination of inconsistencies. Nossiter cites approvingly the French version of this variety of planning, although he recognizes that France's spectacular growth in the 1950's may have been due as much to other, more basic factors.

Nossiter seems less interested in planning per se, than in the establishment

of precise quantitative "economic" targets, against which performance can be measured and costs compared with benefits of alternative programs. Debates over targets would focus attention on society's larger goals and help provide a solution to the problem of legitimacy for economic decision-making in an economy of concentrated economic power. At the very least, Nossiter argues, indicative planning holds out the hope that the quality of both public and private policies will be improved, and that the dominant firms will set target rates of return in the expectation of *expanding* rather than *fixed* levels of output and employment.

One would certainly be hard pressed to quarrel with Nossiter's desire to have us face more squarely and systematically society's larger goals and the principal means for implementing them. The case for planning, however, should not be unduly influenced by the peculiar growth rates of France, Japan, or Norway. Also, basic to Nossiter's proposal is the assumption of self-fulfilling projections, given the proper-sized carrots (subsidies, investment funds, tax benefits, etc.) and the government's power to induce cooperation through sanctions. Nossiter believes the latter would be largely unnecessary to encourage adherence to the plans, since self-interest would encourage business, consumers, unions, farmers, and other groups to follow paths laid down in the model. Active partnership between government and business undoubtedly would produce a greater degree of certainty, thus reducing the risk businessmen seek to minimize or avoid completely. The recognized danger that the planning mechanism will be captured by corporate executives—that business considerations will dominate in setting output and investment targets such that existing market shares and inefficient firms are protected—is suggested by the Japanese and French experience. Nossiter correctly observes that the unplanned American society is subject to the same dangers. The difference, perhaps, is whether the lack of sanction for private, nonresponsible power could be corrected by a technique in which general and particular publics participate in economic policy-making, thus satisfying a hunger which current meaningless fictions only frustrate.

### **Price and Allocation Theory; Income and Employment Theory; Related Empirical Studies; History of Economic Thought**

*Aggregate Supply and Demand Analysis.* By PAUL DAVIDSON AND EUGENE SMOLENSKY WITH C. L. LEVEN. New York: Harper & Rowe, 1964. Pp. xiv, 274.

Modern income-employment theory consists essentially in the analysis of the whys and hows of  $Y$ ,  $\Delta Y$ , and  $\Delta Y/Y$ , where  $Y$  stands for the *level* of national income,  $\Delta Y$  for income *fluctuation*, and  $\Delta Y/Y$  for the *rate* of growth of income. This volume is long on the determination of the former two, but short on that of the latter. The book as a whole would appeal to micro-oriented students of static macrotheory with a considerable amount of training in the neoclassical theory of value and distribution. Its main pedagogic contribu-

tion lies in a novel attempt to add to Keynes' "Principle of Effective Demand" a Ricardian concern with the profit-maximizing, least-cost behavior of individual firms. Thus Part III, which embodies that addition, is devoted to a "post-Keynesian" treatment of the familiar "Ricardo effect," the rest being allocated to "a careful exposition" of the received Keynesian doctrine.

Unlike Joan Robinson and N. Kaldor (the former in a genuine post-Keynesian manner incorporating value and distribution theory into growth theory, and the latter in a like manner introducing income distribution into a non-linear saving function for cycle analysis and policy), Davidson and Smolensky give a rather less post-Keynesian and rather more neoclassical emphasis to the supply side of a market economy. Accordingly, one would be amazed (or disappointed) to discover that the Davidson-Smolensky "aggregate supply function" is devoid of such long-run shift parameters as capital stock and technology, thereby simply and summarily letting those dynamic independent variables be summed in the catchall " $M/A$ -ratio" affecting the general shape (rather than its position) of that supply function. (N.B. p. 133, where the authors nonchalantly state: "we may simply note that we would expect these changes [capital and technology] to primarily affect the aggregate supply function through their effects on the  $M/A$ -ratio.") That star coefficient is, we are told (p. 125), the ratio whose numerator is the wage rate times labor-input and whose denominator is the price index times output (in their symbolism,  $M/A = wN/PQ$ ). This catchall income-distribution ratio is said to affect both the supply and demand functions via the microeffect of wages on marginal cost and that of wage-profit relations on consumption-demand. The possible interdependent effect of the dual cost-demand character of wages upon the stability condition of macroequilibrium is not discussed at all. The result is a familiar short-run supply curve which is upward-sloping, due to the operation of diminishing returns, and which represents that segment of the marginal cost curve which cuts the average variable cost curve from below and through the latter's minimum point—for well-known reasons, albeit at the macrolevel. A passing mention of the linear homogeneous production function of the Cobb-Douglas variety is made by way of expressing an upward-sloping, yet straight, long-run supply curve based on the special assumption of the unitary elasticity of substitution of factors (or constant returns to scale).

For a book that purports to stress aggregate *supply*, it is a great pity that the authors have seen fit to ignore both Leontief's input-output analysis with all its interesting implications for micro-macrolinear programming and Harrod's dynamic theory with all its exciting implications for growth planning. This book, while addressing itself mainly to the problem of employment, nevertheless fails to deal with the Hicks-Patinkin-Kurihara controversy over the relation of the liquidity trap and full employment in static and dynamic conditions and with the Robinsonian model of structural underemployment (due to slow capital growth relative to rapid population growth or to labor-saving automation policies). Joan Robinson's concept of a "golden-age equilibrium" is misapplied to a short-run static equilibrium solution. Some students might find the section on "Social Accounts" by Charles L. Leven and the last

chapter on "Econometric Applications" stimulating enough to pursue further inquiry.

This textbook is technically as rigorous as Hans Brems' *Output, Employment, Capital, and Growth*, though less ambitious in scope. It is substantively less didactic, though formally more esoteric, than Dudley Dillard's *The Economics of John Maynard Keynes* and A. Murad's *What Keynes Means*, not to mention L. Klein's perceptive and provocative *The Keynesian Revolution*.

*Optimales Wachstum und Optimale Standortverteilung.* RUDOLF HENN, GOTTFRIED BOMBACH, AND EDWIN VON BÖVENTER. Schriften des Vereins für Sozialpolitik, New Series Vol. 27. Berlin: Duncker & Humblot, 1962. Pp. 133. DM 19.80.

As the reviewer did, the reader may expect this to be a book on the interaction of growth and location. Such is not the case; the book is simply a collection of three separate and entirely unrelated essays, two on optimal growth and one on optimal location. For this disappointment the publisher rather than the writers must be responsible.

The first essay, by Rudolf Henn, is a straightforward exposition of the von Neumann and of von Neumann-like growth models.

The second essay, by Gottfried Bombach with an appendix by von Weizsäcker, is devoted to defining an optimum growth path in growth models using a Cobb-Douglas production function. In such models, as we know, the equilibrium proportionate rate of growth of output will ultimately depend on three things only: (1) the elasticity of output with respect to labor force, (2) the rate of growth of labor force, and (3) the rate of technological progress. The propensity to consume does not affect the proportionate rate of growth of output but it does affect the level of the growth path of output. Plot output on a logarithmic scale as a function of time on a nonlogarithmic scale. A lower propensity to consume will then shift the economy from one straight-line growth path to a higher but *parallel* one characterized by a higher capital coefficient. Consumption equals output times the propensity to consume, hence has a growth path parallel to that of output. Now the elasticity of output with respect to capital stock is less than one; hence, successive equal reductions of the propensity to consume produce diminishing upward shifts of the growth path of output, so the growth path of *consumption* is first shifted upward to a highest position, but will then shift downward again. That highest position is the optimum defined by Bombach-von Weizsäcker and shown to possess a certain similarity to the von Neumann model in which, as we know, the rate of growth equals the rate of interest. The exposition would have been perfectly clear, had it not referred to the maximization of the long-run *level* of consumption ("langfristiges Konsumniveau"). This reference is meaningless, for there is, of course, no convergence to a stationary level of consumption. Had the authors used the semilogarithmic dia-

gram just referred to, they could have defined their optimum simply and meaningfully as the maximization of the long-run growth *path* of consumption ("langfristiger Konsumwachstumspfad").

The third essay, by Edwin von Böventer, is an attempt to develop further the great German tradition in the theory of location. First a summary and evaluation is given of the contributions by von Thünen (1826), Walter Christaller (1933), and August Lösch (1944). It was Christaller who carried into economics the idea first utilized by the geographers (1916) that the regular hexagon is the polygon of the highest order with which a surface may be filled out completely, hence the beehive-like pattern of his markets around cities.

Neither von Thünen, nor Christaller, nor Lösch bothered themselves with such very real phenomena as migration or regional balance-of-payment equalization, and Böventer takes the first steps to include these in his analysis. More than first steps he cannot take within the space available, but at least he succeeds in showing the reader the majestic order of magnitude of the difficulties involved in the construction of a complete general-equilibrium theory of location. Precisely because of this order of magnitude, it is somewhat surprising that Böventer, unlike Henn, Bombach, and von Weizsäcker, uses no mathematics.

*The Rise and Decline of the Medici Bank, 1397-1494.* By RAYMOND DE ROOVER. Cambridge: Harvard University Press, 1963. Pp. 500. \$10.00.

Although most scholars would consider it one of the most important studies of the Medici bank, Professor de Roover, in his author's preface, discounts his earlier work as "little more than a sketch." Since that time (1948), he has discovered the *libri segreti* or secret account books of the bank, spanning the period 1397-1450, and has fully utilized them in the current work to provide balance sheets and income statements for the bank as a whole and for each of its branches, as well as for demonstrating that the major concern of the Medici was banking and not trade. The new documentation alone would make this an indispensable work, both for the Medici bank and for the period, but De Roover has brought to his study an almost unique combination of skills for interpreting the new material. He is at home in the countinghouse, drawing analogies to modern financial instruments where they illuminate the Medici procedures, but his finely developed sense of the period's history renders him sound and cautious about generalizations supported only by analogy.

De Roover provides an extremely concise survey of European economic history in the fourteenth and fifteenth centuries before proceeding to a more intensive consideration of factors directly relevant to Medici banking history such as usury doctrine, taxation, and coinage variations and types. The early history of the bank is traced from the acquisition by Giovanni di Bicci de Medici

of the Rome branch of the Vieri's bank until its transfer to Florence on October 1, 1397, De Roover's date for the founding of the Medici bank proper. The author shows statistically that as late as 1420 the bank was "a dwarf in comparison" with the Bardi or the Peruzzi of the early fourteenth century and suggests that real growth does not begin until 1423. In 1438 the Medici acquired a silk shop and at varying times several wool shops which could be incorporated into the organization without difficulty because the Medici structure until 1441 was that of a series of partnerships subsumed "in a larger unit similar to a modern holding company." An extremely interesting chart of the organization in 1455 is given (p. 83), showing the silk shop, the cloth shops, and the branches at Geneva, Bruges, London, Avignon, Milan, Rome, Pisa, and Venice, and incidentally incorporating a considerable knowledge of the technology of cloth and silk production.

Each bank balanced its books on March 24 and sent copies of its report to Florence for the benefit of the senior partners. De Roover argues that this was actually done and further that control was sufficient for the partners to specify the amount of assets to be reported for tax purposes, though not to prevent internal deception. The existence of fraudulent books complicates the sources, but the author rightly suggests that, while the balance sheets attached to the tax reports may be suspicious, it is unlikely that the subsidiary reports, involving thousands of transactions, would be faked. The author provides not only records of the whole organization but also those of each branch, studying separately their rise and fall by means of 71 statistical tables.

In his chapters on trade and payments, De Roover sustains the thesis of economic decline during the Renaissance, echoing his earlier work concerning balance-of-payments difficulties between the North and Florence. He makes explicit the labor-saving character of the *torcitoio* or silk-thrower, stating that it "replaced several hundred throwsters doing the work by hand." The importance of the Rome branch, producing more than 50 per cent of aggregate earnings until 1435, and the involvement of the Milan branch with ultimately ruinous loans to the Sforza court further suggest a certain noneconomic undertone in the establishment even during the period of its prosperity. In the sad period of decline following the death of Cosimo in 1464, this undertone becomes the dominant theme, reiterated in each branch. The diversion by Lorenzo of 53,643 florins from his minor cousins and of 74,948 florins of public funds for his personal use emphasizes the noneconomic character of the bank in its later years. The magnificence of Lorenzo is in contrast to the state of the bank.

The book is an invaluable contribution to the economic history of the period. Minor difficulties of style and occasional excessively complex passages should surely be excused as they originate in the difficulties of the material itself. De Roover has rendered a service to the profession by making the Medici records available. He has written a splendid book.

*The Cradle of Colonialism.* By GEORGE MASSELMAN. New Haven and London: Yale University Press, 1963. Pp. viii, 534. \$10.00.

To produce a thoroughly interesting book on early modern colonialism, take a base of competent research in political and economic history, add some biography, and flavor with good writing. This is George Masselman's recipe. And a good one it is. In result, this study will be read with both profit and enjoyment by scholars as well as those ubiquitous "intelligent laymen."

Contending that modern colonialism owes its origins primarily to the Dutch, who "were the first to apply the principle of capital investment to overseas ventures, creating in time the Dutch Empire," Masselman concentrates his attention upon the activities of the Dutch in the East Indies during the early seventeenth century. Fortunately, his narrative begins with a brief but very informative and entertaining account of the salient features of the history of the Netherlands before then. He traces the evolution of economic and political institutions and the rise of the merchant class to a level of prominence and importance it did not achieve until considerably later in other countries. These developments, coupled with advancements in shipbuilding, navigation, and geographic knowledge, enabled the Dutch to push into the East Indies.

Piracy, warfare, intrigue, and other forms of high adventure marked the earlier years of Dutch penetration into the East Indies as they drove out the Portuguese and thwarted British attempts to gain a foothold there. Masselman describes, in considerable detail, skirmishes, battles, and confrontations of the rival merchant adventurers during this romantic period.

Of particular interest to economic historians is his account of the formation of the United East India Company in 1603. This monopoly was conceived mainly as a desirable solution to problems created by virtually unfettered competition which forced up the prices paid for spices in the Indies and depressed them in Europe. It was to have a long, colorful history ending late in the eighteenth century.

One of the Company's most outstanding employees was Jan Pieterzoon Coen, considered by many to have been the greatest Governor General of the Dutch East Indies. Obviously impressed by the unusual qualities of this man, Masselman deftly intertwines a biography of Coen with a history of concurrent related business and economic developments. His engrossing account of Coen's career clearly supports his thesis that Coen saw the Indies as a potential colony, while the directors of the United East India Company were concerned almost exclusively with the Company's affairs, very narrowly conceived. They failed to see that, in the long run, the survival of their firm was dependent upon the broader economic and political developments envisioned by Coen.

Coen foresaw the desirability of permitting other Dutch firms to engage extensively in business in the Indies, but the directors and the Dutch government were opposed. In fact, Masselman notes, the directors clung stubbornly to this position until the Company failed near the end of the eighteenth century.

In an epilogue, Masselman very briefly describes some significant events which occurred between Coen's death in 1629 and the acquisition, by the Dutch government, of all the Indonesian possessions of the United East India Company in 1798. He concludes that the Company's unswerving insistence upon maintaining its monopoly position helped to bring about its ignominious demise. Other developments, perhaps, played more immediate roles. For example, on the one hand, the Company incurred what ultimately proved to be unbearably heavy debts, as it assumed military and other governmental obligations to protect its interests, while, on the other hand, its revenues were reduced by employees who smuggled company merchandise for their own private gain.

The restrictive, monopolistic practices of the Company prevented the rise of a Dutch middle class in Indonesia. They limited migration to the Indies and severely proscribed the business activities in which noncompany, fellow Hollanders could engage. Meanwhile, according to Masselman, the Chinese "gradually began to weld the bond between the Dutch and the Indonesians" and "were thoroughly entrenched" in the many enterprises essential to a viable economy when, in the nineteenth century, Dutch policy changed, opening Indonesia to exploitation by trading and plantation companies.

To conclude, as Masselman does, that at that time "it was too late to create a Dutch middle class," may be correct, but the reader might well ask for the evidence which Masselman does not provide. This illustrates a kind of criticism that an economic historian would make, but, fortunately, at only a few points in Masselman's rather lengthy account. However, this in no way modifies the views expressed in my opening paragraph.

*The Economic History of Modern Italy.* By SHEPARD B. CLOUGH. New York and London: Columbia University Press, 1964. Pp. xv, 458. \$10.00.

Books dealing with economic history can to different degrees meet the needs of readers with varied interests. The value of such books depends, therefore, not only on the amount of information they contain, but also on the manner in which it is presented.

Professor Clough's approach is descriptive, and in the reviewer's opinion, excessively so. Although the wealth of facts that he has collected is as a rule put into organic relationships, the book does not abound with insights, analytical interpretations, and incisive judgments. Hardly any unanswered question is asked. Perhaps it was the author's intention not to draw all of the many synthetic conclusions that as comprehensive a study as this would normally invite. Nevertheless, the detailed data given in the book will prove useful in international comparative studies.

Clough's story begins with the first decades of the nineteenth century and the "age of mobility" that Italy reached through intensive construction of railroads financed by both foreign banks and government budgetary appropriations. Whatever impetus new transportation facilities imparted to the coun-

try's economic growth, the latter's momentum was lost in the middle of that century, largely due to political and military activity preceding Italy's unification in 1861. (Clough refers to it as "the first Italian miracle," which it probably was in view of Italian internal political turmoil.)

In the following decades economic development was resumed and came to depend, as it must in low-income countries, on forced saving (*corso forzoso*). This time it was the textile industry along with shipbuilding and, later, metallurgical production that received primary attention and expanded under governmental tutelage and with the assistance of foreign investment. The author exposes fully the conditions under which "both industrialists and agriculturalists became bedfellows in demanding succor from that agency most readily available to both—the state" (p. 115). Thus one can conclude that nothing has basically changed over the span of decades. In the past as now, there have been two principal reasons for the protection that Italian producers demand: the nation's meager economic resources and the pressure of foreign competition (to which, of course, structural unemployment must be added). By implication, Clough makes a convincing case for the necessity of national governments to assume responsibility for the economic development of new countries and their infant industries.

Among the author's noteworthy items is the fact that the South, the development of which has, since World War II, attracted much international—as well as domestic Italian—attention, has been subsidized governmentally ever since the country's unification. The *Mezzogiorno* "never got less than its percentage contribution to state tax receipts" (p. 169) and was the object of laws passed as long ago as 1904 and 1906. Even during the decade 1871-80 the South received 45.6 per cent of total state expenditures for public works while contributing only 30.4 per cent to tax revenue. Although the Fascist regime never considered adopting a consistent policy to accelerate Italy's economic growth, it was generous in appropriating funds to the development of the southern region.

Clough's account of the aftermath of World War II makes interesting reading, even if it does not seem to do justice to the book's over-all balance. Here, as in other places throughout the book, one fails to see the forest for the trees because of the flood of details. In the chapter on fascism, too much space is devoted to political factors and relatively little to its economic policies ("a tragedy of statesmanship"), although it is these that the chapter's title purports to take up. Description of Mussolini's personality and tactics puts in doubt not only the political wisdom of the king and the entire nation but also the prudence and motives of J. P. Morgan & Co., which in 1925 lent to Italy \$100 million and extended to her revolving credit. Did this and British financial assistance constitute the basis for Mussolini's foolish policy of maintaining an overvalued lira—for prestige reasons—for almost a decade? And was this latter an aspect of the dictator's political quixotism?

"The Second World War and Its Immediate Consequences" (Ch. 8) must be read to appreciate the heavy (and unnecessary) cost to Italy of her partnership with Hitler. She was prepared to wage the extravagant war against the comparatively weak Ethiopia but was overwhelmed by the war on three fronts

to which Germany forced her. Equally hopeless was her position with regard to German economic exploitation during the country's wartime occupation.

Clough's discussion of Italy's postwar reconstruction and welfare state sets forth many of the facts that have become widely known and have earned the country's economic progress the attribute of "a miracle." The story is presented without any argument and without extensive comment, which at least the Vanoni Plan and a few other attempts aimed at an organized solution of Italy's structural economic defects deserve. To the extent that the book does not generally leave room for intensive treatment of technically economic issues, it disposes, altogether too briefly, of the system of Italian capital budgeting, the role of taxation in relation to economic growth, and the country's participation in the European Economic Community, to name a few topics.

Resourceful as this historical book will be found by all students of the Italian economy, it may induce some readers to consider the question of what to expect of similar studies now that both economic thought and policies are committed to the ideas of economic growth and international integration. It seems that after the whole field of economic development has become conditioned for Rostow's stages of growth (if this method has not already become preferred), mere description is outdated and there is an unprecedented need for analytical inquiries capable of shedding new light on both past and future factors which have either facilitated or obstructed economic development of individual nations.

*Economic Trends in the Soviet Union.* Edited by ABRAM BERGSON AND SIMON KUZNETS. Cambridge, Mass.: Harvard University Press, 1963. Pp. xiv, 392. \$9.75.

This book of eight major essays on Soviet economic growth represents the last story of a monumental structure that took over a decade to build. With the exception of Simon Kuznets, whose wisdom and long experience in the measurement of growth were the most fitting qualifications for comparing Soviet and U.S. performance, all the contributors are distinguished students of Soviet economics; most of them have been active in the field since Abram Bergson laid the foundations of his national income project in the late 1940's.

In addition to the main contributors (Bergson, Warren Eason, Norman Kaplan, Raymond Powell, Gale Johnson, Janet Chapman, and Franklyn Holzman), a number of economists who worked on the lower stories of the structure were present as discussants at the Princeton Conference of May 6-8, 1961, at which these essays were delivered. Since the index at the end of the book is signally incomplete, it may not be amiss to list the scholars whose work either contributed directly to the finished products in the volume or formed a link in the elaboration of the underlying data. Among those who also served in this grand enterprise may be mentioned Roman Bernaut, James Blackman, Robert Campbell, Alexander Erlich, Walter Galenson, Raymond Goldsmith, Alexander Gerschenkron, Gregory Grossman, Donald Hodgman, Oleg Hoeff-

ding, Hans Heymann, Jr., Holland Hunter, Naum Jasny, Arcadius Kahan, Jerzy Karcz, Adam Kaufman, Joseph Kershaw, Richard Moorsteen, Warren Nutter, Nancy Nimitz, Dimitri Shimkin, and Lynn Turgeon.

Needless to say, Bergson was the chief architect: on the one hand, his own contribution to the volume, together with his major study of national income published by Harvard University Press in 1961, synthesize a good deal of the material in the other essays devoted to specific sectors and components of the Soviet economy (labor force, capital stock, industry, agriculture, consumption, and foreign trade); on the other, his concepts of measurement and his theoretical notions permeate the work of his collaborators. However, as Bergson is the first to acknowledge, there has been theoretical feedback from some of his talented disciples, including notably Richard Moorsteen, whose work on index numbers influenced Bergson's thinking.

The volume under review marks the substantial progress accomplished since the Arden House Conference of 1952, the proceedings of which were published in *Soviet Economic Growth*, also edited by Bergson. The advance is due in part to more intensive processing and analysis of existing data but also to the vastly increased flow of Soviet statistics, especially for the postwar period. (In 1952, Grossman had no more to go on for his tentative estimates of postwar growth in Soviet national income than a prewar base and changes in the consumption of mineral raw materials and fuels, freight traffic, and nonagricultural employment.) The astonishing thing is that some of the estimates on prewar growth came as close as they did to the more refined efforts of a later day. Grossman, on the basis of Jasny's raw data, had found that national income at factor prices of 1937 rose by 57 per cent between 1928 and 1937; Bergson arrives at an increase of 49 per cent in net national product during the period, also at 1937 factor cost (p. 4).

The essays by Bergson (national income) and Powell (industrial production) confirm the paramount importance for the measurement of growth of the "Gerschenkron effect": series aggregated by means of early-year (i.e., preindustrialization) weights tend to grow appreciably faster than series aggregated by means of later-day weights (because capital goods that were relatively scarce in the Soviet Union in 1928 exhibited faster-than-average growth during the five-year plans along with decreasing relative costs). *Par contre*, Johnson, in his essay on Soviet agriculture in the present volume, concludes that weights of alternative years had little effect on the measurement of farm output.

One of many novel aspects of the present study is the attempt to calculate "total factor productivity" by comparing the growth of conventionally aggregated inputs with actually recorded outputs. This has been done by Bergson for net national product (inputs: employment, reproducible fixed capital, farm land, and livestock), by Powell for his index of "final industrial product" (inputs: labor, fixed capital, inventories, purchases from agriculture, and transportation), and by Johnson for agricultural output (inputs: labor, farm land, purchases from other sectors, capital and livestock). As we should expect, the growth of total factor productivity is greatly influenced by the choice of price-weights for the outputs. Thus, for the period 1928-58, Bergson finds that the

ratio of net national product to aggregated inputs rose by 1.2 to 1.7 per cent per year (depending on the method of aggregating inputs) when national product is measured at 1937 prices and by 3 to 3.5 per cent per year when it is measured as a "composite" (in comparing each year with the base year 1937, output is computed at given-year values). Powell arrives at growth rates of residuals for industry during the same period equal to 1.3 to 1.7 per cent (depending on the rate of return on capital selected) for an output index in 1937 prices and 3.4 to 4.0 per cent for an index using 1928 prices. In agriculture, according to Johnson, total factor productivity, however measured, grew by less than one per cent a year between 1928 and 1959 (the exact results depend crucially on the measurement of labor inputs). For want of data on total factor productivity in the construction and transportation sectors, neither of which is given separate treatment in the present study, we cannot reconcile the calculations for individual sectors with the results obtained by Bergson for net national product as a whole. If, nevertheless, Bergson's results appear rather high, as compared to a weighted average of total factor productivities in industry and agriculture, the reason probably lies in the treatment of labor inputs in the various calculations. Bergson treats the entire labor force as a homogeneous input into national product, whereas Powell and Johnson in effect assign different weights to industrial and agricultural manpower. If a composite input index for the industrial and agricultural sectors were calculated, the aggregated labor inputs for this index would grow faster than Bergson's labor series, inasmuch as the industrial labor force, which grew much faster than the agricultural labor force, would receive an appreciably larger weight than the latter. Bergson recognizes the problem but argues convincingly that "measures of total factor productivity are still of interest if . . . they reflect qualitative changes in labor" (p. 17). Another complicating factor in such a reconciliation is that intersectoral flows, which appear as inputs in the Powell and Johnson indexes, cancel out for the economy as a whole. A reduction in material-input coefficients in agriculture will of course increase the share of industrial gross output available for end uses (i.e., will raise national product), but delicate weighting problems would have to be solved to predict the effect of such a sectoral improvement on total factor productivity for national product as a whole.

There are other reasons as well why the computations of Bergson, Powell, and Johnson are not altogether comparable. Powell and Johnson build up their capital index inputs by adding depreciation to interest charges on net assets to convert the capital stock to a flow. (Powell experiments with alternative interest rates equal to 8 and 20 per cent.) Bergson's index, if I understand his description correctly, is an index of the fixed capital stock, net of depreciation, in keeping with his measurement of net national product on the output side. The Powell-Johnson method is tantamount to weighting the physical stocks of different capital goods by their marginal value products gross of depreciation. (The value of an asset in the capital stock reflects the discounted stream of present and future marginal value products, which are determined in part by the length of its service life, whereas the desired input weight is the marginal value product of the asset during the year where it appears as an input

in the production function. At equilibrium, the gross marginal value product of an asset should equal interest charges on its total value plus depreciation.) To the extent that Bergson's procedure for measuring capital inputs approximates weighting physical assets by their marginal value products *net of depreciation*, it assigns a heavier weight to long-life assets than the Powell-Johnson method.

Another element of disparity is that Bergson and Johnson, for the most part, combine their inputs arithmetically, while Powell combines his geometrically. (Both Bergson and Powell, however, present some of their results with geometric and arithmetic weights respectively.) Since arithmetic weighting implies an infinite elasticity of substitution between inputs and geometric weighting an elasticity equal to unity, one would expect that an index of aggregated inputs with base-year weights would always come out larger when inputs are weighted arithmetically than when they are weighted geometrically. Hence total factor productivity should always come out larger when inputs are weighted geometrically than when they are weighted arithmetically. (These expectations are confirmed by Bergson's calculations for 1950-58 on a 1937 base on page 22.) Johnson's residual must, to some extent, be underestimated, since capital, labor, and land used in agriculture must have less than an infinite elasticity of substitution.

While the calculations of total factor productivity in the volume are valuable as they stand, there is room for further refinements of concepts and methods. Theoretical analysis is called for to gauge the effect of aggregating heterogeneous outputs on the calculations of residuals; there ought to be more study in the same connection of increasing and decreasing returns to scale as well as of substitution elasticities smaller than one. Powell suggests the likelihood of small elasticities "in the short run and for such extreme changes in factor proportions as occurred" (p. 173). It should also be possible to isolate other variable inputs in the aggregate production functions and thereby explain a larger proportion of the growth in observed outputs. (This is being done for human-capital inputs by Nicholas DeWitt.) A more comprehensive coverage of inputs would lend more credence to the widely held belief that the unexplained residuals represent the contribution of technological progress and increased efficiency to growth.

Franklyn Holzman's essay on Soviet foreign trade is imaginative in its treatment and offers the reader stimulating theoretical insights. The remaining papers—by Warren Eason on the labor force, by Norman Kaplan on the capital stock, and by Janet Chapman on consumption—while they present less theoretical interest, are all, as far as I can judge, impeccable in the quality of their scholarship and highly instructive both with respect to the Soviet economy per se and for the comparisons they draw with U.S. experience.

All those readers who, like myself, are consumers of statistics on Soviet economic growth rather than fellow workers in the field should be grateful to the eight expert contributors to the present volume for this work of intelligence, love, and patience.

*Education, Manpower and Economic Growth: Strategies of Human Resource Development.* By FREDERICK HARBISON AND CHARLES A. MYERS. New York: McGraw-Hill Book Co., 1964. Pp. xiii, 229. \$7.50.

The heavy emphasis of a decade ago on capital as the prime mover in economic development has gradually been supplanted by recognition of education, public administration, political leadership, economic organization, and technology as other major elements in economic growth. The present volume, then, is in the mainstream of the new orthodoxy.

While the main concern of the book is with formal education, the authors note that the concept of human-resource development is a good deal broader than this. Considerable attention is given to on-the-job training of people already employed, and to the structure of incentives which motivate people to acquire skills and allocate them among alternative occupations. There is interesting documentation of the fact that in many of the less-developed countries the wage-salary structure has a perverse effect on manpower allocation.

The countries of the world are first sorted out into four educational levels. The criterion used is enrollment in secondary and higher education, calculated as a percentage of the relevant age groups. The stock of educated persons would doubtless be a superior criterion, but stock figures are unavailable for many countries, and current flows are substituted. Educational level, as one would expect, turns out to be strongly related to national income per capita. Level I (underdeveloped) consists almost entirely of African countries. Level II (partially developed) includes mainly countries in Asia and Latin America. Level III (semiadvanced) is a mixture of Asia, Latin America, and the poorer European countries. Level IV (advanced) is the rest of Europe, North America, Australasia, Israel, Argentina, and Japan.

The heart of the book is a series of four chapters, one for each level, which first examine the manpower-resource situation in the countries concerned and then develop a set of recommendations for manpower strategy. The main emphasis in both analysis and prescription is on the formal educational system. To this reviewer, at least, the authors seem to have substantiated their thesis that the problems of educational strategy are qualitatively different at each level, and that in consequence the points at which effort needs to be applied and the desirable allocation of resources among educational levels will also be different. At the same time certain themes recur in successive chapters—notably the dilemma of quantity versus quality, and the key role of secondary education as both the bottleneck through which students must pass to reach higher education and the main source of teachers for feedback into the primary school system. In this connection it would have been interesting to see some use of formal programming methods, with values attached to the human inputs and outputs concerned, and with strategy deduced from some optimizing principle. While these methods have their own limitations, they can provide a useful check on informal intuitions and judgments.

The book concludes with a sophisticated commentary on the problem of setting human-resource targets and of relating manpower planning to over-all development planning. The authors correctly emphasize the inaccuracies inherent in any mechanical projection of occupational demands, the looseness of

formal educational requirements for most occupations, the fact that demand can adjust to supply as well as vice versa, and the fact that prospective short-falls can usually be met in a variety of ways.

This is a major effort in a major field. Its limitations derive mainly from the very large canvas on which the authors were trying to paint, and from the scarcity of quantitative information as well as the difficulty of quantifying policy objectives. Its policy proposals rest on a great deal of observation, discussion, and reading of unpublished government surveys and reports. No one can safely set himself up as either a student or adviser on educational policy without having digested the contents of this book.

*The British Economy.* By SIR ROY HARROD. New York: McGraw-Hill Book Co., 1963. Pp. 240. \$5.95.

All those who know Sir Roy Harrod or who have read his contributions to economic theory or his biographies of Keynes and Cherwell know that his is a mind distinguished but idiosyncratic, speculative but unstatistical, creative not commonsensical, candid but not judicious. A mind justly acclaimed, but singularly ill-fitted, one would have thought, to provide a short balanced account of the British economy for the student and intelligent layman, especially those outside Britain. And so it has proved to be.

Popularization, though usually written with a light heart and the left hand, actually carries heavier responsibilities than writing for one's colleagues. There is little danger of pulling the wool over *their* eyes, as most of us only too frequently discover; but the intelligent layman is almost defenseless, especially when softened up by an array of credentials such as Sir Roy trails behind him. If a review is to provide the nonexpert reader with any kind of defense, hard words must be used wherever hard words are called for; carping and faultfinding should be in direct, not inverse, proportion to the fame and distinction of the author of the book. Such at any rate is the belief in which this review is written.

Perhaps the first thing that strikes one on reading the book is the curious allocation of space among topics. Out of 240 pages, the industrial structure of the economy, trends in expenditure, output, productivity and employment, regional and industrial concentration, and government policies towards monopolies and restrictive practices occupy 18 pages. On the other hand, there are 67 pages on sterling and the monetary system. These provide technical and administrative detail in a profusion that most lay readers would find boring, or incomprehensible, or both. Worse, they are positively misleading because the weapons of fiscal policy are, in comparison, hardly discussed at all. Thus the impression is given that in controlling the economy it is monetary not fiscal policy which has been dominant. Not only is this, of course, quite false, but it will mislead the U.S. reader in a particularly unfortunate way. Perhaps the single most interesting point for an American about the British economy and its management is the possibility of flexible, ingenious, and ef-

fective fiscal policies that British parliamentary and governmental institutions allow.

Easily the best thing in the book is the 30 pages on socialism. Here Sir Roy does what he so conspicuously fails to do elsewhere: he bears in mind the *kind* of ignorance and preconception which an uninformed foreigner is likely to have about the British economy, and he outlines the actual position both justly and persuasively. The way in which he puts the nationalizations of 1945-50 into perspective could scarcely be bettered.

The rest of the book is devoted to the advocacy of a number of theses close to Sir Roy's heart. It might be argued that a book of this kind is not the place for controversy; but the controversy could be made acceptable and stimulating if the evidence were carefully marshalled and if the reader were given some guide as to what was generally accepted and what hotly disputed. Such guidance is most emphatically not provided. There is no bibliography of any kind. More striking, there is only one (very passing) reference anywhere in the text or footnotes to the work of *any* living economist apart from Sir Roy himself. No sources are given for any of the tables in the book: there is simply an unhelpful omnibus footnote at the beginning, listing various official publications used in the work. Thus it is impossible to check and assess properly all the arguments, but one's confidence may be shaken by the fact that in Tables 4 and 5 an elementary howler in comparing U.K. and U.S. statistics has produced serious errors in the figures—serious in the sense that the true figures support exactly opposite conclusions to those which are drawn, from the wrong figures, in the text.

This absence of documentation means that Sir Roy can produce the most bizarre obiter dicta. What can he mean, for example, by the remark on page 182 that "the task of ironing out the business cycle . . . has been pursued more faithfully in the United States than it has in the United Kingdom"? It also enables him to ride his hobbyhorses roughshod over his readers. He believes and argues at great length that the British economy has still not fully recovered from the war because exports have not yet "caught up" with imports. This theory, used to criticize the government for having abolished import restrictions by 1960, he bases on an uncritical acceptance of the prewar position as a norm; an even more uncritical faith in the ability of volume and price series for foreign trade over 25 years to bear the weight of precise numerical comparisons; and a bland disregard for index-number problems. He believes that many of the U.K.'s economic troubles were due to the devaluation of sterling in 1949. This is of course an arguable position; but he does not discuss the main difficulty in arguing for or against it: the Korean War broke out only nine months later, and the effects of this immediately swamped those of the devaluation. This fact is relevant, too, to his discussion on inflation. He outlines a theory to explain the course of inflation in the United Kingdom since the war, claiming rather disarmingly to provide not "an exhaustive analysis, but rather a challenge to research in the United States no less than in the United Kingdom." Not only does he not mention by name any of the many people who have done a great deal of research on this subject, he refers to none of their results and in fact contrives to give the impression that he is un-

aware of what has been done. Since his own approach is ham-handed and amateurish and yields, as he himself admits, some odd results for certain years, the whole business is rather disturbing.

*The Economics of Take-off into Sustained Growth. Proceedings of a Conference Held by the International Economic Association.* Edited by W. W. Rostow. London: Macmillan; New York: St. Martin's Press, 1963. Pp. xxvi, 482. 63s.; \$14.95.

Near the end of the 1960 International Economic Association Conference at Lake Constance on "The Economics of Take-off into Sustained Growth," almost everyone spoke the lingo. Discussants of Kenneth Berrill's paper on "Foreign Capital and Take-off" held that international capital had set up preconditions; developed leading sectors; established progressive, self-financing institutions; and had bridged the gap from a 5 to a 10 per cent savings ratio (pp. 460-64). Yet not one of the authors of the 15 papers other than W. W. Rostow's own accepted his theory of the take-off. Rostow wondered if the rejection occurred because "the introduction of a new concept—especially a new term—is an act of aggression against respected colleagues and friends" (p. xiii). But the terms were not rejected as merely impudent robes for manifest principles. On the contrary, the terms have spread with a success comparable to "multiplier" and "liquidity preference" a generation earlier. At stake is the validity of the theory under the robe of terms and ornamental illustrations.

This long-awaited report of the conference has four parts. First come two general papers, by Rostow and Kuznets, on the merits and demerits of take-off theory. These are followed by attempts to identify take-offs for six countries: the United States (Douglass North); Britain (H. J. Habakkuk and Phyllis Deane); Germany (Wolfram Fischer and Walther Hoffmann); France (Jean Marczewski); Japan (Shigeto Tsuru); and Russia (Alexander Gerschenkron). In the third part, seven papers explore functional aspects of economic growth as related to the take-off hypothesis. Harvey Leibenstein contributes two, one on population growth and another on technical progress. Mogens Boserup and Octavio G. de Bulhões each discuss agriculture. Treatment of capital formation as a whole by A. K. Cairncross is followed by Paul Cootner's paper on social overhead capital and Kenneth Berrill's on foreign capital.

Last comes a 175-page summary record of the debate, prepared by Douglas C. Hague. Illuminating are the introductory comments to some papers, the reactions of Rostow, the final statement by each paper's author, the interim summing up by David Landes, and the reflections at the final session by Robert Solow. But the style of compressed indirect quotation makes at least half the debate unworthy of preservation: "Professor A thought B's estimates of  $x$  too low and  $y$  too high, but in Professor C's view both  $x$  and  $y$  were too high, while Professor D wondered if  $x$  and  $y$  were really as important in underdeveloped countries as in Europe." One gets the feeling of watching tropical fish through frosted glass.

## I

Few of us doubt that modern industrialized economies move in patterns different from preindustrial, traditional economies and that they have therefore gone through some process of transition. But did this process show an unusually marked acceleration in one phase; and, if so, did the acceleration have Rostovian take-off characteristics? At the conference none agreed altogether. The authors on Britain and France thought growth had been a long, steady climb with wars, international trade, and general economic conditions more important determinants of progress than novelties in leading manufacturing sectors. For the United States, Germany, Japan, and Russia, however, some accelerations could be distinguished in scale and significance from other cyclical recoveries. But only Hoffmann writing on Germany sees definite stages of preconditions, take-offs, and sustained growth while nevertheless rejecting the concept of leading sectors. Emphasis on general conditions, especially domestic demand, make North's explanation for the United States similar to those for Britain and France. Gerschenkron identifies a "great spurt" of Dahmen development block growth in Russia after 1885, a view that has much in common with Rostow's sectoral scale and spread effects. Otherwise his theory of the "strains of backwardness" differs sharply from Rostow's, especially in rejecting the preconditions stage. Finally, Tsuru provides a rather Marxist Japanese take-off centering around new social mechanisms for raising invested surplus from 5 to 10 per cent of national income. All writers except Tsuru insist that if they absolutely had to pick a take-off period, it would be earlier than Rostow's, by 5 years for Russia, 10 for the United States, 20 for Germany, 40 for Britain, and 80 for France—at least an orderly progression!

Setting back the initial dates removes a bit of the sting from Kuznets' failure to find much acceleration in aggregate income and investment growth during the periods chosen by Rostow. The data get hazier as one goes backwards in time, disabling alike the friends and foes of take-off. But the gradualists, Kuznets, Habakkuk, Deane, and Marczewski, undo themselves by working both sides of the faint trail. Leading manufacturing sectors, they say, on the one hand, could not cause a discontinuity in growth without affecting aggregate trends. Yet on the other they show that the slow national acceleration mainly reflects different things anyway: trends in international trade, wars, agriculture, and general domestic conditions. But to the very extent that these were important, key sectoral developments in manufacturing had to have repercussions less noticeable in the aggregate. A bold passenger comes to the cockpit in a thunderstorm and takes over the stick without immediate, visible effects on the speed and direction of flight. The real trouble with Rostow's theory is that it cannot predict which passenger will come forward and when. Leading sectors are identified *ex post facto*. To do better one must, as Solow put it, satisfy the great "appetite of a disaggregated economic model for parameters" (p. 471). After all, ten sectors take a hundred numbers, all changing, some very rapidly. So far, therefore, talk of spread and scale effects has not really given us anything more operational than the familiar literary rivalry of the champions of cotton textiles with the champions of rails and steel mills.

When pressed for quantifiable initial conditions, parameters, and rules of behavior connecting key variables, Rostow usually brings up the institutional complexity of growth, especially the role of entrepreneurs and the state. "Growth analysts cannot and should not cut their labors down to the level of simplification, aggregation, and abstraction which the tools of economic theory require, any more than they should restrict themselves to the consideration of those variables only for which reputable statistical measures exist" (p. xxiv). Since much historical evidence is irreducibly complex and unmeasurable but nevertheless trustworthy, one must agree. But by the same token one abandons hope for finding the preconditions in one chronological layer, and in others the emergence and spread of growth-reinforcing institutions. Since one cannot measure and predict the factors that must precede industrial growth, the notion of a preconditions stage suffers, in Gerschenkron's view, "from the double curse of non-operational conceptualization and useless tautology" (p. 166). Several participants concur, but Landes points out that, after all, "growth had to be preceded by a conditioning process of some kind, and this was susceptible to scientific analysis" (p. 394). But if part of this process was the birth of the "Newtonian outlook" in Europe (seeing the physical world as manageable according to a few fixed laws—Rostow's definition, pp. 10, 21, 312), what were the preconditions for that? Can one avoid going back to the peculiar medieval dissonance of half-assimilated Christian, Roman, and Teutonic institutions supplied by an already unusually dynamic technology in plowing, milling, textiles, metallurgy, and other crafts? At least Marczewski wants to go back to "the causes named by general historians a long time ago": wars depressing a potential for growth dating back to the Middle Ages, a potential reinforced by overseas discoveries, the advent of merchant and financial capitalism, etc. (pp. 137-38). This makes good sense and allows more realistic comparison of European growth with Asian and African turbulence and stagnation today. One must depart further from Rostow's stages than either going back to the familiar Industrial Revolution idea or on to Kuznets' substitutes, "the late pre-modern phase" and the "early growth phase" (pp. 42-43).

So little is left of final self-sustaining growth that "self-" drops out of the book's title. Kuznets asks the right questions: In what sense was growth *not* self-sustaining during the take-off? Does not all growth have self-limiting effects? Does it mean that these are finally outweighed by self-sustaining impacts? Does generating those not always mean a struggle? (pp. 39-40). Rostow had already agreed, "There is, then, nothing automatic and easy about the inner mechanics—the logistics, as it were—of sustained growth. [But] on present historical evidence, it appears fair to say that the larger psychological, social, technological, and institutional changes required for a take-off are such as to make it unlikely that we shall see a true lapsing back" (pp. 10-11).

## II

Among the functional papers, Cootner's on social overhead capital is brilliant, an example of what growth analysis should be, combining history and

theory with high relevance for policy. Transportation, power, and communications are denied a special prerequisite role but are made an integral part of economic expansion, necessary but themselves induced. Cootner shows that previous conclusions depend less on assumptions about immobility, scale, gestation, and durability than on objective uncertainty and imperfect foresight. Both uncertainty and scale, according to him, affect social overhead expansion less in industrialized than in primary-producing and -exporting nations. Development of material-exporting countries depends on diminishing returns in resource exploitation in advanced nations. Hence, the analysis can explain the out-of-phase alternation of overhead investment in the two types of area, presumably still evident in Labrador and Venezuela. At the same time, for countries developing via import substitution, it puts Hirschman's case for lagging social overhead spending there in a broader framework.

Another good paper is Berrill's demonstration that foreign capital played virtually no part in the take-offs of Britain, France, Germany, Finland, and Japan. Timing suggests that foreign capital was not an initiating factor in the United States, Canada, New Zealand, Australia, Sweden, Norway, Denmark, and Russia. In any case, it was only a "small" fraction of total saving, about one-fifth (p. 286), and not nearly as important as the coming of foreign technicians and machinery (pp. 291, 466).

The papers on capital, agriculture, population, and technical progress explore whether there is something about their behavior that is consistent with a discontinuous acceleration at the beginning of industrialization, and if so, whether for all or only under a few circumstances. For capital formation Cairncross finds that differences in urbanization and prevalence of capitalist institutions limit the relevance of European records for Africa and much of Asia. Some increase, however, though not necessarily a rapid doubling, of the savings ratio must form part of the process of growth. But if this process is under way, with investment needed and remunerative, why should a physical shortage of capital persist? Cairncross believes the mechanism by which a financial bottleneck makes itself felt has been inadequately discussed because it is too much taken for granted (p. 247). He also finds that almost any relation between capital and income growth is feasible, with causation possibly running in either direction. Once he goes too far with this. His argument that "There is, of course, no necessary inconsistency between a rising incremental ratio and a constant average ratio" (p. 253) depends implicitly on measuring the two by different price indices or on using a gross definition for one and a net definition for the other.

Mogens Boserup's analysis of "Agrarian Structure and Take-off" may be, as in Hans Singer's view, "a landmark in the development of growth economics" (p. 428). The first part amounts to the position that agriculture will not lead in economic development, except perhaps for short periods, but that if ignored, it can drag down the whole process. The second part identifies four basic structural changes (British, Eastern, French, and Mediterranean) that stress the fate of the tiller and the kind of person who "takes care of the entrepreneurial function." Changing the traditional cultivator's outlook, conquering agriculture from within, is not as easy as British tiller eviction or East-European serf "emancipation." Since development in South Asia is likely to be no more

than a shift from "Mediterranean" share-croppers to "French" peasant owners, industrialization is likely to take longer than in Northern Europe.

But if Boserup shows how little speed agriculture will allow for industrialization, Leibenstein believes that population growth now demands higher speed. In Europe population was primarily induced and "raced" against capital formation and aggregate income growth. Advances in public health, etc., have made population growth more of an exogenously determined obstacle in underdeveloped countries, thus raising the initial hurdle that must be overcome and demanding a sharper take-off as the escape from stagnation. Unlike Cairncross, Leibenstein seems to link capital formation, income, and population too rigidly to one another, making any unfavorable position of this constellation augur "sustained stationariness." If the modernization and institutional changes that make "a true lapsing back unlikely" occur in one region of a country, among one group or more, or in a few sectors, then aggregate population growth and its effects can be misleading about lack of progress.

### III

On one important point Rostow had much support: his emphasis on technological progress. The regular flow of new production functions is the main criterion of take-off. As Landes put it, "The heart of the system was the analysis of technological diffusion via leading sectors and linkages" (p. 391). Other participants had their own version. Cairncross speaks of "the process of innovation that lies at the root of economic progress" (p. 241). Leibenstein begins his paper on "Technical Progress, the Production Function, and Development" by noting that very few would quarrel with the statement that "the technological inventions of the last few centuries are the prime factors that make it possible for a country to shift from low levels of income *per capita* to high levels of income per head" (p. 186). But what follows is an ingenious contrivance about a minor aspect of technical change in a setting of dubious realism but consistent with the take-off hypothesis.

Leibenstein seeks to prove that capital formation, factor substitution, technical progress, and the inducement to invest reinforce one another where capital is abundant but not where it is scarce. At the capital-scarce level of development practically no production alternatives are said to exist, and chances for developing new ones would be low even if producers had the knowledge to search or innovate. The reverse of all this fits where capital is abundant. With isoquant geometry one can then show that a lot, but not a little, more capital would be worth saving and investing: a take-off.

Leibenstein's view of technical progress is that of Adam Smith, a process of simplification. The division of labor makes for more specialized, simpler processes; and the simpler they become, the more easily can one see the next potential improvement. Finally when the capital-labor ratio is high, one can substitute nonhuman mechanical energy for human or animal energy (pp. 193, 425). But doesn't the addition of power tools and the like happen in workshops that in most industries are still at the labor-intensive end of the spectrum? Long before the latest capital-intensive levels are reached, will purely manual work have been reduced to a few auxiliary operations? Meanwhile, the other phases of production will have become more interrelated, rather than simplified, and

the specialized worker at his post will have less and less knowledge of the unfavorable repercussions, which have nevertheless grown more likely, if he introduces a change. Where volume is large enough and capital cheap enough, not subdivided but complex, balanced and integrated, continuous-flow processes will predominate.

Questions of scale are curiously left out of the paper, and in the discussion Leibenstein insists that, if he were to rewrite it, he would not bring in scale (p. 425). Yet volume is a much more important determinant of technique than relative factor prices—in the sense of comparing the plausibility of changes with the magnitude of effect. Beyond critical levels, the most advanced capital-intensive methods used anywhere are consistent with the lowest known wage-interest ratios. Entrepreneurs in practice face the question of capital-labor substitution almost exclusively with the simplest theory-of-the-firm question: "How much volume do I need to amortize the equipment?" Volume shares this role only in that comparatively small range of a few processes where mechanization is possible but adopted or avoided mainly because of effects on quality. Where extreme weights, temperatures, pressures, voltages, poisonous fumes, and similar circumstances are qualities essential to production, human participation is drastically limited. Since science is more likely to add than to remove these, capital-labor substitution tends to lose significance in the course of economic development. Moreover, scientific research mostly concerns that element which often looms largest in a firm's books, though cancelling in the aggregate: materials. Research on novel ways of creating, substituting, or treating materials is mostly justified by the hope of gains larger than those to be had from merely changing capital-labor ratios. Capital-labor substitution is therefore neither within the intent nor the direct capacity of a large portion of scientific progress, though even here it may occur as a by-product. Discussion of production functions diffused during early industrialization cannot realistically abstract from the effects of science and economies of scale.

Like other good conferences, this one discussed three kinds of papers: cogent recapitulations of years of scholarship, method-centered reports of work-in-progress, and new questions boldly posed. Like the first Zeppelins that cumbersomely took off at Lake Constance, Rostow's theory may soon be a museum piece. But the problem of the transition remains, as did once the problem of flight, and the contributions stimulated by Rostow are important markers on the runway toward solution.

*Resources and People in East Kentucky: Problems and Potentials of a Lagging Economy.* By MARY JEAN BOWMAN AND W. WARREN HAYNES. Baltimore: Johns Hopkins Press for Resources for the Future, 1963. Pp. xxiv, 448. \$10.00.

The East Kentucky region studied in this volume is defined as the 36 counties east of the Cumberland escarpment. By contrast with the rest of Kentucky, it is poor. Compared with national per capita income and unemployment rates, it is depressed. East Kentucky's economic development was based largely on the

exploitation of its coal resources, wood processing, and subsistence agriculture. Declining employment opportunities in coal mining, depletion of the forest resources, and stagnation of the agricultural sector have resulted in a high level of unemployment, low per capita incomes, and heavy outmigration.

East Kentucky's plight is provocative of many questions. The region, containing 737,000 people, rather clearly has a comparative and absolute disadvantage in almost everything. The development of efficient, large-scale farms and/or of manufacturing on any significant scale would be economically inefficient owing to the topography of the region and to the high cost of transportation to outside areas. The educational structure is appallingly bad. Outmigration during the 1950-60 decade was at an annual rate of 3.68 per cent. Despite the high natural rate of population increase (1.97 per cent), population declined from 874,000 in 1950 to 737,000 in 1960.

This raises interesting questions with regard to the internal economic structure. What impact does declining population have on local industry? What happens to local asset values and the tax base? What policies would be most efficient in ameliorating the situation?

The facts of East Kentucky's distress are well known. Professors Bowman and Haynes present a study that "may best be described as an historical-ecological approach to the diagnostic analysis of underdevelopment." The volume is divided into two parts. Part I—the major part of the book—consists of a detailed examination of the economy of the region and is written by Mrs. Bowman; Part II contains a study of the East Kentucky coal industry, written by Mrs. Bowman and Mr. Haynes. The first three chapters are intended to provide an overview of the region's resources, economic structure, and historical development. Chapters 4 through 7 focus on coal, manufacturing, over-all postwar employment, and wood processing. Chapters 8 and 9 assess the likely future growth of employment. Chapters 10 and 11 are concerned with population, migration, and education. The final chapters of Part I evaluate policy alternatives. Part II traces the history of employment, output, and profitability of the East Kentucky fields. For those interested in selective reading, there are summaries at the end of each chapter.

Unfortunately, the book has several major shortcomings that render it less useful than enumeration of chapter headings would indicate. In the first place, the use of data leaves a great deal to be desired. Related to this, and even more serious, the framework of analysis is somewhat deficient.

In the 436 pages of text, there are 73 maps, 95 tables, and 68 figures. Not only does the reader become lost in a plethora of data, but frequently the figures presented are not as meaningful as fewer and alternative numbers might have been. For example, nowhere is the employment structure of the entire labor force given. Instead, insured labor force data for 1956 are presented. Even then, only the mining and manufacturing breakdown is given. These employees account for less than half of insured employment and less than one-third of the (smaller) 1960 labor force. In this case, as in many others, the entire state of Kentucky is used as a basis of comparison. Unless one is conversant with the national figures or with Kentucky's structure contrasted with the national, use of this basis leaves the reader with an inadequate frame of reference.

Even more fundamental, the data presented are not brought together in any meaningful over-all framework. There are no regional flows data, and no examinations of trade, service, or agricultural sectors.

Part of the reason for this inadequacy may be the awkwardness of a 36-county unit and the fact that the authors conducted much of their research prior to the publication of the 1960 *Census*. They did, however, have and utilize some data from the 1960 *Census*. Greater reliance even on the 1950 *Census*, as opposed to piecemeal sources, would have greatly improved the manuscript. *Census of Business* data could have enabled some analysis of the service and trade sectors.

Data problems and the more substantive limitations of the volume are closely interrelated. By this reviewer's calculations, 30 per cent of the 1950 and 20 per cent of the region's 1960 labor force were engaged in agriculture. There is, however, no chapter, or even major section, devoted to analysis of this troublesome, low-income sector. Indeed, the authors are finished with the subject at the end of Chapter 1 when they concluded that, "East Kentucky agriculture . . . offers no promise for the future." Failure to distinguish coal-associated (unemployment) poverty from agricultural (low-income) poverty leads to some disappointing gaps in the analysis.

Likewise, the treatment of outmigration leaves a great deal to be desired. In the first place, it is hardly mentioned in the three summary chapters, yet it is fundamental to any understanding of the region's economy. My computations suggest that the unweighted averages of county 1950-60 outmigration and natural increase rates show sharp contrasts between the counties classified as agricultural and those classified as coal counties. Outmigration proceeded at 4.98 per cent average annual rate from the coal counties and at 3.14 per cent from the agricultural counties. Yet no breakdown of behavior between the rural farm, rural nonfarm, and urban population was undertaken. Indeed, throughout the book, rather than analyses in terms of, say, "coal counties," "agricultural counties," and "manufacturing counties," to suggest but one possible breakdown, the text frequently degenerates to a county-by-county description of data. This not only results in confusion to the reader unconversant with individual counties, but also in *ad hoc* explanations of differences.

Similarly, the estimation of the region's future is deficient with respect to migration. Estimates of the 1976 employment gap are computed on the assumption of no net outmigration from 1960 onward. The prospects for East Kentucky involve a choice between raising per capita income and attempting to maintain population. The faster is outmigration, the higher will be per capita income, and conversely. Failure to stress this trade-off between population and per capita income is a fundamental defect of the policy section.

The policy section (Chapters 12 and 13) focuses heavily on the need to improve education. Although it is recognized that migration increases with educational attainment, no consideration is given to means of speeding outmigration. Rather, the authors suggest that Kentucky leaders resign themselves to the fact that outmigration will continue. Acceptance of the inevitability of outmigration would undoubtedly be a distinct improvement. One wonders, however, whether this goes far enough. The authors believe that area redevelopment and other depressed-area programs will not solve East Kentucky's

problem. If this is the case, speeding outmigration would appear to be the alternative. While educational upgrading is important in this regard, surely other measures might also be considered.

Similarly, there is little systematic inspection of local government revenues and expenditure needs. In view of declining population, the questions associated with a shrinking local tax base would appear to be an important policy question. Although the authors contend that East Kentuckians are reluctant to spend on education, they do not consider local revenue problems, aside from recognizing the need for outside financial assistance.

The treatment of coal-associated problems is far more satisfactory than the overview of the economy. While the focus on coal mining may have been overdone, the industry analysis in both Part I and Part II is distinctly superior to the regional analysis. National conditions in the industry, the instability induced in East Kentucky by the presence of many high-cost marginal operators, and the effects of union wage agreements on the region's segment of the industry are treated carefully and exhaustively.

Despite the shortcomings enumerated, economists who have engaged in regional research in other regions will find many points of interest. Contrasted with East Kentucky, the problems of most other regions experiencing net outmigration seem negligible.

*Development with Stability—The Indian Experiment.* By S. L. N. SIMHA. Bombay: Vora & Company, 1963. Pp. vii, 131. \$2.50.

Mr. S. L. N. Simha, who has served the government of India in a variety of capacities, has written a slim little volume on India's recent economic development. For over a decade India has been committed to a type of development planning that has attempted to raise per capita income with the maximum price stability. The emphasis, according to the author, has been on "democratic development" with a mixture of public and private enterprise. And while both government regulation and the "free market" have been utilized to allocate goods and services, the three five-year plans have placed a great deal of responsibility on fiscal and monetary controls to stimulate the allocation of resources into capital accumulation. Simha concentrates his attention on these monetary and fiscal policies or, as he expresses it, "the financial aspects of the Indian development effort" (p. 11). Basically the book is a summary review of the three five-year plans and covers the years 1951 through 1962.

The first plan began in 1951 and was essentially a preparatory plan for those to follow; it owed much to the Bernstein mission of the International Monetary Fund. It was extremely modest and placed great emphasis on financial discipline and price stability. Taxes were raised and monetary expansion limited. Investment outlays in the government or public sector were relatively small (at least as compared to subsequent plans), and the general decline in prices indicated to the author that perhaps too little was done. However, the average increase in real national income per year of 3.5 per cent was "by no means an unsatisfactory performance" (p. 33). Perhaps less encouraging was the fact that during the last two years of the plan real national in-

come growth declined to 2.5 per cent and 1.9 per cent. No figures were available on unemployment or underemployment.

The second five-year plan covered the years 1956-61 and represented a somewhat greater effort. There was much attention paid to growth (public outlays were increased for a projected 5 per cent annual growth in national income) and less attention was paid to price stability. Bank credit expanded and there was a 32 per cent increase in the money supply. More foreign assistance was utilized (21.5 per cent of investment), which helped to offset the decline in export markets. At the same time that this expansion was under way, a series of taxes was imposed in an attempt to decrease consumption rather than profits. Interest rates were raised in an effort to increase the cost of capital, but not for the purpose of limiting the availability of bank credit. Wholesale prices rose about 30 per cent and the cost of living rose by about 24 per cent during this period. Unfortunately, the growth in real national income (4.3 per cent average) was only slightly greater than in the first five-year plan. As the author says: "[this was a] not too satisfactory rate of growth of real national income" (p. 80).

The third five-year plan has been designed for the period 1961-66 and, in general, appears to continue the policies established in the second plan. Bank credit has been allowed to expand about as rapidly as during the previous period. Interest rates have been raised and taxes have again been boosted in an effort to hold down the growth in consumption. Foreign assistance is expected to increase slightly to about 24 per cent of investment. Increased military outlays, due to the recent dispute with China over the India-China border, are expected to bring about even greater effort to raise taxes and curtail consumption. And, while only two years of the third five-year plan are covered in this review, the author points out that "the first thing that needs to be mentioned about the Third Plan so far is the disappointing rate of growth of national income" (p. 87). National income increased only 2.1 per cent during the first year of this plan, and the second year has been estimated at about 2.0 per cent. On the whole, however, the general rise in prices has been curtailed.

The author does not say whether or not India's rather orthodox financial policies continue to enjoy the support of the International Monetary Fund, but certainly the Indian government appears to have paid close attention to those rules designed to limit inflation, extract the maximum rate of savings from the economy, while at the same time attempting to provide investment opportunities for private capital. As the author points out, the rate of profit and dividends as a proportion of sales have shown significant increases, in addition to the rise in price of corporate shares. "[Expansion of private capital] owes a great deal to the atmosphere of dynamism and growth generated by the Five Year Plans" (p. 114). Salary and wage costs, on the other hand, have been held to a relatively constant proportion of sales.

Simha's own conclusions regarding India's policies for economic growth appear to be somewhat mixed. He feels that one of the lessons to be learned from India is that a "mixed system can work rather well, particularly in stimulating growth" (p. 128); and he appears to support the Planning Commission's statement that "it will be seen that over the past 10 years, the country has made considerable progress in every branch of national life" (pp. 128-29).

Nevertheless, he concludes by saying that "it is now generally admitted that the progress of the Third Plan so far is disappointing in terms of rate of growth of national income. The dynamism of the Five Year Plans appears to have been dormant for some time" (p. 129).

To this reader, Simha's review of the Indian five-year plans reveals the pathetic eagerness of the government to obey all the rules of sound finance and the tragic inability to make progress that would give some hope of raising one of the world's lowest standards of living to a tolerable level in any reasonable period of time. If this experience in India (a country presumably about ready for the take-off into sustained growth) is the best that orthodox finance can accomplish, it would seem doubtful that any other underdeveloped country will see here a serious plan for economic growth.

### **Statistical Methods; Econometrics; Social Accounting**

*Méthodes statistique de l'économétrie.* By E. MALINVAUD. Paris: Dunod, 1964. Pp. xiv, 634. F 86.

"Statistical Methods of Econometrics" is in the tradition of Diderot and d'Alembert. (Fortunately, the printer has treated the present work with substantially greater kindness.) Following his predecessors, E. Malinvaud combines a careful critical survey of the field with many original contributions—some large, some small, but all illuminating. His style is vivacious and his text sparkles with a *clarté* which is only partly French and mostly Malinvaud.

The book is divided into five roughly equal parts: Part I gives a general introduction to econometric models and methods, including a first-rate geometrical introduction to simple regression and an entire chapter reviewing almost all recent work on the consumption function. Material on consumption is used to good effect to illustrate identification problems, the inconsistency of ordinary least-squares estimates of the marginal propensity to consume, distributed lag models, aggregation problems, and the like. Part I (and especially the chapter on consumption) serves to motivate the discussion of the remainder of the volume and to demonstrate the relevance to concrete problems of the varied body of techniques presented subsequently. Notable features of Part I are the extraordinarily clear discussions of "bunch map" analysis and its uses, of principal components analysis including its relation to orthogonal regression, and of recursivity. There is some discussion of the problem of model specification errors and the importance of finding statistical procedures which are robust in the face of such errors, but few conclusions relevant to subsequent discussion are drawn, apart from the general warning (p. 145) that the choice of a good model is as important as the choice of a correct statistical procedure.

Part II (four chapters) deals in detail with the general theory of linear multiple regression and tests of linear hypotheses. A geometrical analysis of simple regression is presented and extended, and results in an intuitive exposition of considerable clarity. Malinvaud here follows the work of the French mathematician and statistician, G. Darmois, whose papers do not seem to be

well known in this country. Advanced material, such as the Stein result on the nonadmissibility of least-squares estimators, is introduced in a nonrigorous but clear fashion at several points. Such simple but useful results as the standard error of a constant term in a linear multiple regression are derived. Zero-one variables are introduced, but unfortunately are not used to clarify the nature of the analysis of variance and covariance. Indeed, if this section of Malinvaud's book can be criticized, it is because he fails to use the obvious partitioning of zero-one and other independent variables to bring the analysis of variance and covariance under the general regression framework. The problem of multiple confidence intervals is treated in great detail. The section closes with discussion of various complications such as heteroscedasticity, nonlinearity, omission of variables, and the problem of infinite residual variance. In connection with the latter, it is perhaps worth noting that John Wise has shown that the consequences for the asymptotic properties of least-squares estimates are far from disastrous.

The third part of Malinvaud's book deals with problems of nonlinearity and with errors-in-variables models. It contains, as an appendix to the chapter on nonlinearity, a beautiful discussion of convergence in probability and the properties of probability limits. This is a subject of great importance in econometrics, but not well treated in accessible form elsewhere. The chapter on nonlinear models discusses the minimal distance estimators of Wolfowitz extensively; these are in turn related to some of the simultaneous equations methods in Part V. The method is applied to the problem of estimating a system of demand functions (which, due to their derivation from a common utility maximization process, embody numerous internal constraints). The next chapter is entirely devoted to errors-in-the-variables models, the importance of which had been suggested earlier in Malinvaud's discussion of the consumption function and Friedman's permanent income hypothesis. Weighted regression, the work of Geary, Reiersøl and Sargan on instrumental variables, and Liviatan's work on the consumption function are all treated at some length.

Part IV is entirely given over to time-series analysis and associated problems including distributed lags. This section perhaps contains more original material than the others. The first of the five chapters in this section deals with stochastic processes generally. The autocovariance function and the spectral distribution function of a stationary process are introduced. The Wold decomposition of any stationary process into a purely deterministic and a linear, and purely nondeterministic, process is given, and the alternative representation of the latter by equivalent moving average or autoregressive schemes is discussed. There is a brief but suggestive discussion of the prediction problem along Wiener-Hopf lines. Some readers may at first be confused by Malinvaud's short discussion of *ergodicity*, which appears to equate that property with *stationarity* generally, until they notice that the discussion is restricted to *linear* processes. The following chapter deals with various inference problems, including nonparametric tests for trend, tests for independence (a particularly fine treatment of the Durbin-Watson statistic is reserved for the following chapter), and the decomposition of time series and search for hidden periodicities. There is even a brief—but very brief—treatment of the recent literature on spectral estimation, although regretfully little indication of the uses to which such techniques may be put in economics. Serial correlation in

regression residuals is the subject of the third of the five chapters. Here we find discussion of the Durbin-Watson statistic, of the asymptotic properties of ordinary least-squares estimates (including Wold's 1952 results on correction of error variances), and of various methods for handling residual serial correlation. Aitken's generalized least squares is, however, omitted and the treatment of prediction with autocorrelated residuals leaves much to be desired. The reader may wish to supplement Malinvaud in this area with material from Goldberger.<sup>1</sup> The final two chapters of the section contain extensive and partly original discussions of the estimation of autoregressive models, and the closely related topic of distributed lag models. The biases of least-squares methods are fully treated, and the discussion of lag models is exceptionally complete, covering the work of Fisher, Koyck, Nerlove, Solow, and Theil and Stern, with many little added touches. A minor objection to Malinvaud's treatment in this chapter is that he views the major differences between various types of models generating distributed lags as largely statistical in the sense that differences are reflected in the residuals of the estimating equations. This point of view leads to erroneous conclusions in models containing more than one equation; distributed lags due to expectational causes, for example, are then the same for the same variable in different equations, whereas different variables in the same equation may have other distributions of lag.

The final section of Malinvaud's volume deals with simultaneous equations models and methods. An introductory chapter discusses identification problems, reduced forms, and recursive models. A particularly good discussion of production-function estimation problems is given. Next, various estimation procedures are introduced in terms of a variety of simple models. Two-stage least squares are shown to be simply related to instrumental variables in the overidentified case. An especially notable contribution is the clear statement of the requirements for recursivity and a convincing demonstration of the biases resulting from ordinary least squares when the diagonality of the contemporaneous residual variance-covariance matrix is not realized. There follows a rather technical but quite complete discussion of identification, mainly along the lines of Koopmans and Hood, but also including some of F. Fisher's recent generalizations. Minimal distance methods are effectively applied to the discussion of estimation in the next chapter, and T. M. Brown's recent "simultaneous least squares" is shown to be a special case. The closing chapter deals with the usual range of techniques, albeit with omission of three-stage least squares. Minimal distance methods are again used to illuminate the treatment, and the chapter contains a clear treatment of limited information along the lines it was first presented by Anderson and Rubin.

It is perhaps clear from the foregoing that Malinvaud's book is at once more advanced and of broader coverage than most existing books in the field. It assumes a knowledge of matrix algebra and basic statistical theory, and it develops a number of important special topics rather fully. It might therefore be used following a text such as Johnston<sup>2</sup> or to supplement Goldberger.<sup>3</sup>

*Measurement in Economics: Studies in Mathematical Economics and Econometrics in Memory of Yehuda Grunfeld.* By CARL F. CHRIST, MILTON FRIEDMAN, LEO A. GOODMAN, ZVI GRILICHES, ARNOLD C. HARBERGER, NISSAN LIVIATAN, JACOB MINCER, YAIR MUNDLAK, MARC NERLOVE, DON PATINKIN, LESTER G. TELSER, AND HENRI THEIL. Stanford: Stanford University Press, 1963. Pp. xiv, 319. \$10.00.

This is a reasonably good book. Some of the papers contributed deserve close and repeated attention. The reviewer is of course expected to comment on the uneven quality of the essays. However, the quality variance is submerged under a potential reader's uneven interest in the material presented.

The book has been well organized into four parts. Part I contains the contributions to the "Theory and Measurement of Consumption" made by Milton Friedman, Nissan Liviatan, Jacob Mincer, and Don Patinkin. Zvi Griliches, Yair Mundlak, and Marc Nerlove wrote the papers in Part II under the heading "Theory and Measurement of Production." Part III covers monetary phenomena and contains papers by Carl Christ and Arnold Harberger. The last part is devoted to statistical theory, and presents the essays contributed by Leo A. Goodman, Lester G. Telser and H. Theil.

The reviewer's attention is certainly more unevenly distributed over the book than the quality of the papers. A passing reference to Part IV should not be interpreted as a negative reflection. The papers are competent, but of somewhat special interest. Still, Leo Goodman's analysis of movements and comovements of time series and Lester Telser's work on transition probabilities might be usefully consulted in particular contexts.

The papers by Friedman and Liviatan deal with the permanent income hypothesis of the consumption function. Friedman's essay emanates from the somewhat obscure methodological situation found in the *Theory of the Consumption Function*. A higher level hypothesis of the consumption function in terms of our inherited choice theory was tentatively sketched in Friedman's book. Furthermore, the book developed two distinct empirical hypotheses. One hypothesis was cast into the form of an error-in-variables model. The other supplemented the specification of a linear homogeneous relation between real consumption and expected income with an expectational hypothesis. Following the basic ideas of the higher level sketch, neither one of the empirical hypotheses related consumption with income measured in the standard manner. In either case the difference between the theoretical and observed income requires some conceptual clarification and involves some subtle interpretations. These issues were not adequately worked out in the book, and Friedman attempts to supply the necessary analysis. In particular, his paper deals with the role of unanticipated changes in measured income in the context of a "permanent income hypothesis." His analysis also attempts to establish a connection between the two subhypotheses developed in the book. The paper is stimulat-

ing, but does not resolve the analytical issues completely.

Liviatan's paper develops a careful appraisal of the subhypothesis cast in the mold of an error-in-variables model. It is an excellent paper and highly recommended. The author exhibits an articulate awareness concerning the logical structure of his evaluations. The role of auxiliary empirical assumptions is carefully noted and their place relative to the hypothesis under consideration explicitly assessed. His procedure is imaginative and resourceful. However, the appended comments by Friedman clearly reveal some of the unsettled issues emanating from the inadequate (and unavoidably indirect) semantic characterization of "theoretical income" in the context of an error-in-variables model.

Part I contained two more papers. Patinkin shows his usual analytic craftsmanship combined with a pervasive misconception of "positive economics" in a discussion of consumer surplus. Jacob Mincer's paper, however, contributes substantively to the volume. His material contains some imaginative applications of economic analysis to the demand for transportation services, the supply of labor, demand for domestic servants and for children, and the effect of information costs on price and income elasticities.

The part on production theory opens with a paper by Griliches on the role of the capital stock in the investment function. The author discusses carefully several concepts of the capital stock and appraises their comparative performance in the explanation of investment behavior. His major conclusion, though, appears somewhat obscure, viz., "that most of the argument favors two different measures of capital simultaneously, one approximating . . . capital as a quantity . . . of machines and the other measure approximating . . . capital as the current value of the stock of machines." Griliches may be correct, but I fail to recognize the economic rationale for this conclusion. Moreover, some of the statements in the initial sections bearing on the nature of the investment function in the absence of an explicit incorporation of the capital stock appear to disregard that the class of stock-adjustment hypotheses is not the only possible class of investment hypotheses. Still, I found the paper useful and very informative.

Marc Nerlove's essay appraises the returns to scale in the electricity industry. A cost function is derived from the specification of a Cobb-Douglas type production function and the stipulation of cost minimization relative to given outputs. The resulting cost function exhibits a parameter which may be interpreted as a measure of the "degree of returns." The empirical estimation confirms the prevalence of increasing returns. A finer analysis indicates an inverse relation between firm size and "degrees of return." Some of the results, however, are difficult to believe for an economist. Several elasticities of output with respect to capital would suggest that capital is almost irrelevant or that capital accumulation should even be avoided. The author emphasized, however, the inadequacy of the capital cost data. This of course renders an interpretation of the results quite difficult. Furthermore, the phenomenon observed may actually be interpreted in the context of an alternative hypothesis which simultaneously incorporates a rate and a stock of output (i.e., the expected program or similar concepts) and actually denies the occurrence of increasing returns with respect to the rate of output (in the sense of a partial derivative). Under this alternative hypothesis the phenomena observed by Nerlove would

yield no evidence in favor of the existence of "increasing returns." Nerlove worked his case carefully and explicitly, but the case of "increasing returns" still remains very open.

The last group of papers, dealing with substantive economic issues, were contributed by Carl Christ and Arnold Harberger. Both papers are informative and useful. Of particular interest in Christ's study of demand for liquid assets is the ascending order of income elasticity associated with more inclusive concepts of liquid assets. The evidence also supports the predicted operation of interest rates in demand behavior, but some puzzling problems arise whenever interest rates are separately incorporated into the regression. Harberger's paper on the inflation mechanism in Chile evaluates the comparative significance of "money push" and "wage push." I find his analysis thoughtful and interesting. However, he will invite the wrath of all those who believe in the superiority of large equation systems. The evidence presented strongly confirms the relevant occurrence of a money push. The existence of a lag in the money push is also revealed. The wage push appears to occur, on the other hand, only with a marginal significance. The author accompanies the regressions with a detailed discussion which clarifies and interprets the results.

In summary, the book should be welcomed. Several papers may be usefully assigned to graduate students and even be usefully absorbed by their teachers (before writing that textbook).

*Natsional'ny dokhod Ukrayins'koyi RSR v period rozhornutoho budivnytstva komunizmu.* (National Income of the Ukrainian SSR in the Period of Development of the Construction of Communism.) Edited by O. O. NESTERENKO *et al.* on behalf of the Institute of Economics of the Academy of Sciences of the Ukrainian SSR. Kiev: Academy Press, 1963. Pp. 335. Rbl. 1.60.

Unlike the states in our union or in other federations, the national republics of the USSR have both enough statistical data and practical need to compute their own national incomes. Since 1957 their economies have been planned and administered as separate units, and national income accounts are used for such purposes. Signed by 25 authors and six editors, the volume under review is the first comprehensive work since 1925-30<sup>1</sup> on methodology and the problems of actual national income of one of the Soviet republics, the Ukraine.

The concept of national income used in this book is the traditional Marxian "net material product." It continues to exclude most of the services as "unproductive," in spite of the fact that the proportion of the so-called "productive" labor in the Soviet economy decreases and that of the services increases, as it does everywhere else in the industrialized world. Net material product is calculated for each industry and sector by the value-added method. To this they then add the volume of the turnover tax prorated for each industry in

<sup>1</sup> Estimation of the Ukraine's national income was quite advanced before 1930. Since then there was only one admittedly crude attempt. Cf. V. Holubnychy, "Das Volkseinkommen der Ukraine in den Jahren 1940 und 1954," *Sowjetstudien* (Munich), no. 2, March 1957.

which it originated. They consider this tax to be the same thing as profits, i.e., part of the Marxian "surplus value." The book also proposes an innovation: to impute rent to the land, but this is not done in practice yet.

According to the above method, the Ukrainian national income in 1960 was 27,046 million rubles, or \$30 billion at the official rate of exchange. It was growing by 7 per cent per year, but that growth has been slowing down; 58 per cent of it originated in industry, 26 per cent in agriculture, and the rest in the transportation of goods and in commerce (the balance of foreign trade was not counted, however). The Ukrainian share in the total national income of the USSR amounted to 19 per cent. The per capita income was 7 per cent below the USSR average. (If services were included, the per capita national income of the Ukraine would be about \$835 today.)

Calculations of the primary and final distribution of the national income in the book are not quite complete and involve many problems, including some political ones. For example, the authors conclude that 78 per cent of taxes collected in the Ukraine by the federal government (four billion rubles a year!) are not returned to the Ukraine in federal expenditures and investments. The final use of the Ukraine's national income according to the book consists therefore of 71 per cent going for consumption, 23 per cent for investment, and 6 per cent for deficit appropriated by Moscow and transferred "to construct Communism" in some other parts of the USSR. The book also discusses the problem of price differentiation inside the USSR and points out that some additional portion of the Ukraine's national income is transferred to the rest of the USSR via prices. It does not arrive, however, at any estimate of this portion. Another problem which remains unsolved is that of the correct allocation of the turnover tax volume between the Ukraine and the rest of the USSR.

The book contains a lot of valuable statistics which are not available elsewhere. In fact, its data on the components of the Ukraine's national income are more comprehensive than those published so far for the USSR as a whole. There are also some revealing explanations that may be new to the students of the Soviet economy. It is stated, e.g., that the surpluses in the USSR federal budgets are used to expand the credits of the State Bank. Many students suspected, on the contrary, that they were additional hidden expenditures for defense. The book ends with a summary in the Russian language. It is a great pity that the summary is not in English or in some other Western language.

### **Economic Systems; Planning and Reform; Cooperation**

*Cuba: The Economic and Social Revolution.* Edited by DUDLEY SEERS.  
Chapel Hill: University of North Carolina Press, 1964. Pp. xx, 432. \$7.50.

This is the first substantial treatment of the economic aspects of the Cuban Revolution to appear in English. It is indispensable for students of Latin American economic development, and particularly for students of problems of economic planning in primary export economies. The book is made up of four sections: (1) a long essay by Professor Seers on the economic and social background of the Revolution and a tentative assessment of the over-all perform-

ance of the island's economy from 1959 to 1962; (2) a detailed analysis of the changes in the structure and operation of agriculture placed in the context of a survey of prerevolutionary agricultural problems, written by a Chilean economist, Andrés Bianchi; (3) an exhaustive account by Richard Jolly, an English economist, of the pre-1959 educational system and progress in that field since the downfall of Batista; (4) and Max Nolf's (another Chilean economist) study of Cuban industrial stagnation before the Revolution, together with a description of industrial organizational changes and planning in 1961-62.

Inevitably the essays are uneven, overlap, and differ somewhat in tone and treatment; the volume shows signs of being put together in a hurry. As Seers explains, "what really decided the issue [whether or not to do the book, given the lack of data and rapidity of change] was that information is so badly needed on what is one of the most important political developments in this century." Important areas of the "economic and social" revolution are slighted, thus the volume's title conveys more than is intended; labor developments are given cursory treatment; progress in the field of health receives little mention; there is practically nothing on social services, culture, and recreation. With limited time and resources, the editor chose to focus on what he considers to be the key areas; this is not intended to be a comprehensive, much less definitive, study of the Revolution, as Seers himself points out.

The authors' major findings challenge the official U.S. view that Cuban socialism rests on dangerously shaky economic foundations. A careful appraisal of the available data shows that from 1959 to 1962 "total real disposable income rose considerably in the country districts but perhaps hardly at all in Havana" (p. 37). A shortage of statistics prevented a sector-by-sector analysis, but the chief sources of the expansion are enumerated; the nearly total elimination of rural seasonal unemployment; increases in land under cultivation; the dramatic expansion of social investments in housing, education, and health. On top of this, the abolition of rents and the relative improvement of rural wage rates redistributed income from city to countryside. Food shortages in late 1961 and 1962 (the food situation has improved significantly since then) are correctly attributed to a rise in autoconsumption. This rise was generated partly by a breakdown in the distribution system when the trade sector was nationalized and partly by deterioration in the terms of trade between country and city; organizational problems associated with inexperienced state management of the People's Farms in the sugar, cattle, and rice sectors; and drought. Thus there is no real support for the thesis that Cuban agrarian reform was and is a failure. Quite the contrary, Bianchi carefully shows that organizational changes in key sectors of agriculture were the precondition for crop diversification and expansion, and full employment of the rural labor force. Implicit in the analysis (the authors rarely give political questions their due, or make them explicit, thus viewing economic and social changes divorced from the popular mood, counterrevolutionary forces, U.S. foreign policy, and so on) is the fact that there was mass support for these structural changes; Seers is correct when he writes (p. 60) that the Revolution is "to a great degree irreversible."

Turning to industry, Nolf shows that prerevolutionary industrial develop-

ment lagged well behind objective possibilities (the growth of the market, raw materials, and so on). Although he slights Batista's industrialization program of 1953-57 (an analysis of its limited success would reveal much about the problems of the old economy) and fails to explore fully the unfavorable implications of market organization for industrial development, his conclusions are incontestable. Thus the emphasis that the 26th of July Movement placed on industrialization in its initial programs in 1957-58 was carried over into the revolutionary period, where it underwent considerable alteration. Nolf concentrates on investment planning and industrial policy in 1961-62 and reproduces the first "plans" which were later either modified or discarded as containing too much "subjectivism." These plans projected very optimistic trends and finally awarded high priority to heavy industry, specifically chemicals, steel, and automotive plants. The projections were lowered and investments in heavy industry (excepting chemicals) were postponed as balance of payments problems, shortages of raw materials and technical and administrative personnel, and other difficulties multiplied. In mid-1963 Cuba adopted a "new course" (which Nolf failed to foresee through no fault of his own—Cuba is an island of quicksand for those who attempt short-run predictions) which shifted emphasis to sugar and cattle and the industries complementary to these sectors. Only with respect to electrical power and maritime investments have Cuban planners remained on a straight course; outlays in these areas have risen steadily since 1959.

The problem of sources is the central problem for the authors; only Jolly had full access to needed sources, and he receives more space in the volume than the others; thus the data problem shapes the study itself. It is not likely that Cuban education from 1959-62 will ever again receive the comprehensive descriptive treatment which Jolly gives it. He explores quantitatively and qualitatively Cuba's many new educational programs, describes the rapid expansion of primary education and the all-out war against illiteracy in 1961, and probes the new technical education programs for working adults. Weighing the costs and benefits of the massive outlays on education, Jolly hedges on a final judgment, but his materials support the view that the inevitable waste involved in such a program is more than offset by the cultural and potential economic gains for the Cuban people.

*Economic Planning in France.* By JOHN HACKETT AND ANNE-MARIE HACKETT, with a foreword by Pierre Massé, Commissaire Général du Plan. Cambridge: Harvard University Press, 1963. Pp. 418. \$7.00.

This study is devoted almost entirely to the procedural aspects of French planning. The Planning Commissariat, the ministries, and the other bodies involved in creating the Plan, are described in detail, including changes and developments in their nature and functions since 1946. The Plan is then followed through the various steps of the drafting process. Finally, the mechanics of implementing the Plan are surveyed. The authors bring to bear an extensive knowledge of the French planning machinery and provide a vast amount of information on this complex and changing process.

The matters of principal interest to economists, such as tests of the soundness of the Plans, how closely they are followed, and what the effects of planning are, for good or ill, on the French economy, lie outside the scope of the book. The authors' reasons for limiting the scope are suggested by these lines in the chapter, "General Conclusions": "If there was no Plan, what difference would it make? We have gradually come round to the view that it is not, on the whole, a very helpful means of approach. It depends too much upon an impossible reconstruction of 'things as they might have been' as France's whole post-war development has been coloured to a, varying, extent by the Plan. Moreover, it is usually put by the observer with his own preoccupations in mind" (p. 357). That is to say, attempting to assess the effects of planning is both empirically impossible and subject to a possibly biased choice of criteria for evaluating the performance.

The empirical impossibility of evaluating the effects of planning does not prevent the authors from repeating, in the next paragraph, the popular and unsupported conclusion: "It is very largely because of the achievements of the planning experiment since 1946 that securing a rapid rate of growth is not the arduous problem for France today that it is, for very different reasons, for the United States or the United Kingdom."

The impression one receives from this book, as well as from most other works on the subject, is that French planning is primarily a ritual. For those interested in the intricacies of the rites, this book will be valuable. Those who want to know whether the ritual really contributes anything to the French economy, and, if so, what there is about France that demands the planning ritual when other economies (Germany, Japan) get along as well or better without it, will have to search elsewhere for the answers.

*Gospodarka Europejskich Krajów Socjalistycznych (zarys rozwoju w latach 1950-1975).* (Outline of the Economic Development of the European Socialist States from 1950-1975.) By ARTUR BODNAR. Warsaw: Książka i Wiedza, 1963. Pp. 391. Zł. 35.

Artur Bodnar's book merits the attention of students of the communist (or, as the author prefers to call them, socialist) economies in spite of the fact that the main body of his historical statistics ends, for the most part, with data for 1958-59. Also the study covers only those socialist countries of Eastern Europe, plus the USSR, which belonged to the (Communist) Council for Mutual Economic Cooperation (COMECON) around 1960.

In the author's words, the purpose of inquiry is to trace the economic developments in the respective socialist states, analyze their regional interdependence, and compare their economic achievements with those of Western Europe and the United States. To this end, Bodnar has painstakingly collected statistical material directly from the original sources of the socialist countries and has presented it in more than 200 tables. Interestingly enough, he has been less inclined to use similar official Western statistics. When it comes to an intersystem comparison, his data on the capitalist economies are taken, with only a few exceptions, from the studies published in Moscow or Warsaw.

The book is divided into seven parts, but the inquiry is focused on industrial activity, which is presented in Part IV and comprises about one-third of the entire analytical study. Another third is taken up by agriculture and trade, presented in Parts V and VI, respectively. Economic aggregates—services excluded—are scrutinized in the opening Part I. Part II offers a rather superficial and deficient summary of the natural-resource situation, while Part III discusses the COMECON countries' human resources and manpower requirements in the future. In the concluding Part VIII, the author speculates about the consequences of rapid economic progress in the Communist orbit on the economic configuration of the world.

Discussion in each subdivision opens with a review of the COMECON economy in its totality and in the contest of the intercountry relations. It continues with an examination of the particular subject matter within the framework of each individual socialist state.

Among the most significant aspects of Bodnar's study is an indication that, as the Soviet bloc countries approach the stage of high industrialization, structural changes in their economies create problems not unlike those facing the capitalist countries. One is the growing dependence on imported raw materials. Attempts to ensure the future supplies by bilateral resource-development agreements have not proved very successful. There is a marked hesitance, as Bodnar remarks, in the less-developed states to commit large parts of their resources to export industries. Moreover, a kind of anti-import phobia, obviously connected with their recent stage of predominantly agricultural, closed economies, prevents systematic application of the principle of low-cost production throughout the bloc.

Some investment decisions and efficiency of execution may also be questioned, hints Bodnar. Thus, during 1951-57, Rumania spent about 35 per cent of all industrial investment in an attempt to augment output of its indigenous fuels, i.e., chiefly petroleum, with disappointing results. Relatively small expenditures on research and development as well as low labor productivity throughout the bloc are other sore points mentioned by Bodnar.

All this notwithstanding, the author calculates that the COMECON states, and especially the USSR, will become the dominant factors on the world market during the 'seventies. Bodnar sees the U.S. industrial production surpassed by the USSR by 1972, at the latest.

Evidently in the past the COMECON area recorded a rapid growth in industrial output, although not in the living standards that Bodnar accepts as the ultimate criterion of economic progress and intersystem competition. Moreover, his statistical and analytical confrontation of both systems can be questioned on several grounds. For example, it is far from clear how Bodnar has derived his index of total economic growth and industrial production of all socialist countries. Further, his intersystem statistical comparisons suffer from a timelag, about 10 to 15 years, as Bodnar's conclusions usually rest on the socialist economies of 1970-75 and the capitalist world of 1958-1960. Besides that, he takes for granted that the planned high rate of growth of communist economies in the next 10 to 20 years will be attained.

Within five months after the book was published, the results of the first four years of the seven-year plans were proving him wrong.<sup>1</sup> Thus, between

<sup>1</sup> *Zycie Gospodarcze*, March 17 and 24, 1963. *Vestniki Statistiki* (Moscow), March 1963, pp. 39-48.

1958 and 1962, the annual rates of growth of national income declined in the USSR from 12 per cent to less than 6 per cent; in Poland, from 5.6 per cent to 2.5 per cent; in Czechoslovakia, from 8 to 0.5 per cent, etc.

How far all this changed the outlook for the future, as envisioned by Bodnar, we shall have to wait to see. But some comfort may be drawn by Western economists from the fact that the vicissitudes of reality play the same havoc with forecasts no matter whether they are based on estimates of market forces or on the flat decrees of an economic plan.

### **Money, Credit and Banking; Monetary Policy; Consumer Finance; Mortgage Credit**

*Money.* By M. L. BURSTEIN. Cambridge: Schenkman Publishing Co., 1963. Pp. xvi, 908. \$13.25.

This is a massive book, over 900 pages long, and replete with explanatory notes at the end of each chapter as well as appendices attached to some of the latter. Broadly, it follows in the footsteps of such contemporary works on money as those of Shaw, Hart and Kenen, and Trescott with their emphasis on the application of economic theory to monetary problems and the relationship of financial to real variables. It goes beyond them, however, in its attention to and coverage of advanced macroeconomic theory in which are included such topics, among others, as Leontief's synthesis of Keynes and Fisher, the Chicago School's modification of the Leontief model, the Duesenberry system, Rose's formulation of the Harrodian problem as well as the Robinson and Kaldor growth models, Hicks's "real" trade-cycle theory, the Friedmanian Quantity Theory, the Gurley-Shaw hypothesis, and the rudimentary dynamics to be found in Keynes's *Treatise on Money*. Also, the book goes well beyond these texts in its explicit formulation of general equilibrium and process analysis and the use of mathematical models. The calculus and matrix algebra are employed extensively, not only in the macrotheory section of the work, but also in the chapters and notes on commercial and central banking theory and policy as well as balance-of-payments theory.

In spite of the considerable richness and diversity of the material and other positive aspects of the work mentioned at the conclusion of this review, the book is exasperating on several counts. For one thing, it abounds in poor pedagogical techniques. Thus, it is badly organized with theory and policy somewhat indiscriminately interspersed throughout, the traditional velocity-of-money chapter followed only some 300 pages later by a chapter on the neo-quantity theory of money, and the latter suspended in limbo and separated from the income-expenditure chapters by one on central banking policy. Along similar lines—and such illustrations could be multiplied—in undertaking an introductory discussion of money's role as a liquid store of value (pp. 4-5), Keynesian liquidity preference is mentioned without ever being defined and assumptions made about the reader's ability to grasp the functional relationship of liquidity preference to different types of monetary standards and in-

voluntary unemployment, assumptions and relations which are not systematically explored until some 500 pages later.

More important, while the author is in good company in prefacing his work with the hope that "many undergraduates will find these materials manageable," even a cursory reading suggests that the material contained therein is much too difficult to be taken seriously by him or by others as a potentially successful undergraduate text either in a course in "Money and Banking" or one in "Macroeconomics." While such exaggerated claims may delight book publishers, they do not lend luster to the economics profession. Indeed, such claims tend to create a carnival atmosphere, nine-tenths of which are compounded of patent nonsense and an eye to the till, while the remaining tenth represents an ingenuous hope that the elixir being offered miraculously may prove serviceable. This book goes even further than most by including, among its potential customers, not only undergraduates and, quite legitimately, graduate students and professional readers, but also bankers and financial analysts. Perhaps commercial bankers could "find many sections of the book pertinent to their everyday business" could they but grasp the very high order of abstraction to be found throughout and the ability to translate such abstractions into meaningful propositions. A good case in point is where the author deals with the theory of the bank as a firm (pp. 190-93). A purely formal statement mathematically couched in terms of maximization subject to side conditions is offered in these pages with the solution technique, nonlinear programming, not presented. As the author himself says, "our model can, by virtue of its *emptiness*, accommodate a large number of bank portfolio problems" (*italics mine*). I am afraid that this is only too true so far as the commercial banker is concerned.

Nor is the going much better for central bankers. While the author does delve into such contemporary monetary issues as the role of nonbank financial intermediaries, the bills-only doctrine, the lock-in effect and the term structure of interest rates, these are analyzed in almost debonair fashion and certainly are not germane to the main body of the text. In fact, from the many pages devoted to the subject, it is apparent that the author's real love—and strength—lies in the exploration and analysis of the innumerable variants of income theory rather than in problems of policy. The trouble lies not in such a bona fide division of intellectual labor as in the fact that so much of the former discussion is devoted to abstruse issues of doctrine, issues which can only result in policies of little practical import for central bankers. Thus, after some 250 difficult pages, which include four approximations to income theory and several appendices, the author concludes this section of his book with a chapter entitled, "The *Pure* Theory of Central Bank Policy" (*italics mine*). This consists primarily of spelling out the policy implications of the many income variants within a general equilibrium framework. One can do no better in criticizing this type of endeavor than to quote from a recent article by Brunner and Meltzer on this matter ["Some Further Investigations of Demand and Supply Functions for Money," *The Journal of Finance*, Vol. XIX, No. 2, Part 1 (May 1964), p. 240]:

For almost two decades a virtually impenetrable curtain has separated two groups of monetary economists. One group has engaged in a learned

and apparently interminable discussion concerned with the subtleties of Pigou effects, Lerner effects, and Keynesian effects, the existence or absence of money illusions dichotomization of real and money prices, Hicksian weeks, and related esoterica. . . .

It does not require an astute observer to notice that many of the issues that agitate monetary theorists have little or no bearing on the policy issues discussed. The analytical frames constructed and vigorously disputed with plausible and counterplausible arguments yield neither propositions clarifying the policy issues nor verified propositions directly applicable to policy decisions.

In spite of the criticisms leveled above, the book merits scrutiny, if not as an undergraduate or trade text, then as a reference work for advanced graduate students. Burstein exhibits not only a high degree of knowledge and competence of advanced monetary theory, but his undoubted, if at times misplaced, flair for the English language and striking the happy phrase stand him in good stead when discussing such traditionally dry subjects as monetary and banking history. These do tend to come to life in his hands. Further, he does not hesitate to tilt lances in engaging fashion with theories he considers unsound or misleading, as witness his critique of the Friedmanian quantity theory of money. While he tends to exaggerate Friedman's much-quoted and misquoted statement on income velocity as an empirical constant (pp. 729-34), he does not hesitate to take on at the same time the real issue of the so-called stability of the demand function for money. His critique of such single-equation models in terms of the now familiar identification problem (pp. 772-75), while not new, is well worth reading, along with many other little gems to be found scattered throughout this very uneven and peculiar book.

*The Economics of Banking Operations—A Canadian Study.* By JOHN ALEXANDER GALBRAITH. Montreal: McGill University Press, 1963. Pp. x, 510. \$7.75.

This is a book for serious students of the economics of banking for its fundamentals are treated at an advanced level. There are seven chapters, each of which is a study in itself. The first chapter, "The Nature and Consequences of Domestic Banking Operations," considers the activities of commercial banks as borrowers, lenders, and investors. The sense in which commercial banks are similar to and differ from nonbank financial institutions is fully explored. Those interested in the issues raised by Professors Gurley and Shaw should find much to interest them here, although on the crucial question of whether new controls are necessary or desirable little is said.

Chapter 2 "The Economics of Banking 'Output,'" begins with a useful summary of the literature on the availability doctrine and then develops a theory of lending behavior, assuming that banks either maximize profits or maximize profits from loans. Credit rationing in modern banking systems is found to be rare, and variations in excess cash are held to alter security holdings rather than loans.

"Competition, Profits, and the Capital Accounts" is the title of the third

chapter. Here the author argues that even though competition between commercial banks will lower their profits in the short run, the results of this competition may restrict the growth of nonbank financial institutions, and bank profits in the long run may be greater.

The implications of monetary policy for bank profits are also considered, and it is held that bank profits are probably increased by a restrictive monetary policy and reduced by a policy of ease, although the converse cannot be ruled out. The analysis is questionable, however. Restrictive monetary policy is said to raise interest rates. But if an economy is operating at full employment with a constant money supply, an increase in investment demand would raise the equilibrium rate of interest and generate inflation. If the inflation is prevented by a contraction in the stock of money, in the new situation the rate of interest would be higher than it was originally, but not necessarily higher than it would have been if the stock of money had not been reduced; tight money need not raise the equilibrium rate of interest.

Chapter 4, "Interregional Banking Transactions and Operations," considers the pros and cons of branch versus unit banking. Most of the arguments are shown to be fallacious. The author concludes, however, that branch banking probably makes a greater contribution to the stability of the economy, since under this system regional shifts of deposits need not cause secondary repercussions. But since he also argues that, under contemporary conditions, banks that gain reserves buy government securities, while banks that lose reserves sell them, the secondary repercussions under a system of unit banking are trivial.

The fifth chapter is concerned with international banking transactions and operations. It considers mainly banking arrangements under flexible exchange rates. The sixth chapter is about government financial operations. The impact of government deficits and surpluses on economic activity is assessed, and the possibilities of shifting government deposits between the central bank and the member banks in order to alter reserves is extensively discussed.

In the final chapter, "Central Banking," the author is first concerned with the definition of a central bank. A bank becomes a central bank if it operates without consideration for its profit position; it is a question of motive. Both open-market operations and the discount rate are considered at length. On whether the discount rate should be changed by formula or by discretion, i.e., whether changes in the discount rate should serve as a signal, Dr. Galbraith suggests a compromise. Ordinarily the rate should be altered by formula, but when a signal appears desirable, the formula should be abandoned for discretionary changes.

One of the important conclusions of this chapter is that the basic principle of central-bank control is the manipulation of excess *cash*. In considering the English banking system, however, the author discovers that a modification or special interpretation of this generalization becomes necessary. The English banks are supposedly subject to a liquidity requirement; they must keep 8 per cent of their deposits in cash and at least 30 per cent in the combined form of cash, money-market loans, and bills. But it is maintained that bills are perfect substitutes for cash, since the Bank of England supports this market. A reduction in the cash requirement without a change in the so-called

liquidity requirement would temporarily create excess cash. But the only consequence of this would be an exchange of cash for other liquid assets.

The issue is clarified if it is said that the English banks have a 30 per cent reserve requirement and receive interest on 22/30 of their reserves rather than both a cash and liquidity requirement. The basic principle of central-bank control can then be said to be the manipulation of excess *reserves*.

There is also an appendix on the expansion of banking systems. The usual explanation of the way in which a commercial banking system expands when it has excess reserves assumes that excess reserves are not averaged. But if excess reserves can be averaged, so that banks tend to keep average excess reserves zero, Galbraith shows that the standard explanation of the expansion process is far from satisfactory.

This is a new book about old questions. It must be judged mainly by its treatment of the literature, its clarification of obscure points, and the freshness of its observations. By these standards it is excellent. So many controversial topics are discussed that everyone will not be able to agree with everything. But until some other able economist surveys this literature again and reflects upon it, the present work will be of great value to experts and will be required reading in graduate courses in banking.

*Banking and Monetary Studies*. Edited by DEANE CARSON. Homewood, Ill.: Richard D. Irwin, Inc., 1963. Pp. xiv, 441. \$6.00.

The Comptroller of the Currency has commemorated the Centennial of the National Bank Act of 1863 by sponsoring the publication of a book of 23 essays on banking and monetary subjects. These subjects include banking and monetary history, monetary policy, banking structure, competition and regulation. Many of the essays also contain a generous dose of monetary theory.

Space limitations prevent me from going into a detailed discussion of each contribution. It is sufficient at this point to note that the various contributions differ in quality. Most are very good indeed. Some could have been improved if additional references had been consulted. Others probably simply reflect the busy work schedules of their authors—all the more serious in view of the sponsor's claim that "all of the selections are original contributions written by outstanding economists exclusively for this book."

For purpose of setting the record straight regarding American banking conditions in the years before and after the Civil War, Bray Hammond and Philip Cagan present the reader with two very useful essays. According to Hammond, banking up to the Civil War was not as bad as some people would have it. And Cagan's appraisal of the pre-1914 National Banking System is a very different and far more interesting story than the caricature of that system in standard money and banking textbooks.

Hammond's emphasis on the failure to recharter the Second Bank as the reason for the U.S. monetary muddle in the 1830's is overdrawn. For the most part, U.S. troubles originated abroad. A world-wide rise in prices coupled with capital inflows into the United States enabled the country to expand its stock

of money and prices without incurring external difficulties. This expansion occurred primarily in the form of bank notes and deposits. When external prices declined and capital inflows ceased after 1839, an internal contraction was the only alternative if the United States was to continue on the specie standard and fixed exchange rates. The subsequent U.S. adjustment in the period 1839-43 took the form in part of a 25 per cent decline in the number of banks, including the demise of the Second Bank (under Pennsylvania charter since 1836) in 1841.

John Culbertson's argument that many errors in economic policy since World War II apparently can be traced to the fallacies of the "banking school" rather than economic theory will probably appeal to most economists. I would argue, however, that much of what is wrong with U.S. banking and monetary institutions can be traced back hundreds of years. The specie standard, fixed exchange rates, and "real bills" doctrine are but illustrations of defunct ideas that still sway a considerable portion of the banking fraternity. One effect has been to create an intellectual disaster area in U.S. banking and monetary institutions.

The implication of David Meiselman's novel argument that a rise in interest rates may in fact intensify the U.S. gold outflow should come as quite a shock to those in the grips of the "banking school" mentality described by Culbertson. Meiselman bases his argument in part on the close association between the quantity of money and economic activity in the United States. Canadian data would also tend to support his argument.

The interesting contribution by Deane Carson and Ira O. Scott, Jr. dealing with commercial bank aversion to risk should be useful to people concerned with economic development. The results are consistent with the important role that commercial banks play in development. An independent study employing member bank data for the period 1950-60 tends to support their argument.

*Financing Economic Development.* By ANTONIN BASCH. New York: The Macmillan Company, 1964. Pp. xiv, 334. \$6.50.

Professor Basch's objective in this book is to analyze the role of financial institutions and financial markets in the saving-investment process in underdeveloped countries. The main problem is how underdeveloped countries can best use their financial structures to increase their saving rates and, hence, their output growth rates. Towards this end, the book is organized around government saving, private saving, and foreign saving; and the author discusses each topic by drawing on the recent experiences of many countries, principally those in Asia and Latin America. He has apparently left few stones unturned in digging for the facts, and he has dug deeply, but his analysis of these facts is, most of the time, rather shallow and, in a few instances, grossly defective.

In the first part of the book, the author takes up the problem of government saving. He surveys several Asian and Latin American countries and concludes

that there are so many pressures for increases in current expenditures by government, and so little income elasticity to the tax systems, that it is doubtful if many countries can generate sizable surpluses of tax receipts over current expenditures. Such surpluses are kept low in many countries, according to the author, partly because government funds are used to subsidize public enterprises which seem to have chronic deficits.

In the second part, the author feels that private saving should be increased and new savings habits acquired by the people. "The policy should be one to guide people increasingly to deposit savings at financial institutions or to invest them in financial assets. This object requires, of course, patient and continuous work and must be supported by appropriate financial institutions" (p. 106). It also requires, the author states, monetary and financial stability, and many countries in South America are censured by him for failing this test. Basch surveys financial institutions in quite a few underdeveloped countries (and Australia), and discusses capital markets in these countries and the possibilities of increasing direct finance. He attempts to link up the financial structure of each country with its saving-income ratio (e.g., an efficient financial structure should raise the saving-income ratio), but not very much emerges from these comparisons.

The role of foreign saving in economic development is discussed in the third part of the book, first in terms of foreign government saving and then in terms of foreign private saving. Here the author evaluates the recent activities of some international financial institutions; he is pessimistic about the prospects for private foreign investment; but he is hopeful about increasing governmental "soft" loans and grants to underdeveloped countries. A final part of the book briefly summarizes the progress achieved (quite a bit in places) and the task ahead (difficult and challenging).

The book contains a wealth of information on financial aspects of development, and it has useful references. It suffers, however, from the author's inability to make very much of the facts, facts, facts. The book is especially weak in its analysis of the financial role of government in economic development. Under what circumstances should a new governmental financial institution be established? What is the role of government in fostering capital markets? When should public enterprises run deficits? The author fails to answer these and similar questions satisfactorily because of the absence of any theory of efficient resource allocation, including a framework for analyzing social vs. private goods, and social benefits and costs vs. private benefits and costs.

Another serious weakness in the analysis is the author's neglect of the money supply as a means of saving. The money supply almost never appears in any of the analyses of saving, nor in the numerous tables that add up the savings of various countries. This omission greatly distorts a good bit of the discussion.

In sum, the author has gathered together a great deal of data in a very useful way, but he has failed to tell us what an optimum financial structure looks like.

*Política financiera.* By ANTONIO ORTIZ MENA. Mexico: Editorial PESA, 1962. Pp. xv, 112. 26 pesos.

*Visión crítica retrospectiva del crédito en México.* By HANÍBAL DE ITURBIDE. Mexico: Publicaciones Especializadas, S.A., 1963. Pp. 136. 26 pesos.

*Mercado de dinero y capitales.* By ALFREDO LAGUNILLA IÑARRITU. Mexico: Publicaciones Especializadas, S.A., 1963. Pp. 124. 26 pesos.

These three little books provide useful glimpses of Mexican finance and financial institutions. Antonio Ortiz Mena, Mexico's Secretary of the Treasury, and Haníbal de Iturbide, a prominent commercial banker, discuss the problems of credit and monetary policy from opposite sides of the fence. Alfredo Lagunilla Iñárritu, a professor of the National University, tries to sum up everything about money markets and capital markets, but succeeds chiefly in illuminating the present state of these concepts in Mexico. No great scholarly effort went into the writing of these volumes—the first two are collections of speeches, while the third is an expanded set of lecture notes. Their interest lies in their authorship and the points of view they exemplify.

The speeches of Ortiz Mena and Iturbide are worth reading together. They make excellent counterpoint. Indeed, bits of each can be arranged to form a dialogue that sums up the main issues in Mexican banking policy. In such a dialogue, Iturbide keeps pointing out that the policies of the government are self-defeating; that its encouragement of the development of a capital market is vitiated by the activities of the treasury and of the government banks. He pleads for a change in the holding-company role of the Nacional Financiera, for an easing of the extraordinarily high reserve requirements imposed on commercial banks (up to 100 per cent), for actual rather than verbal encouragement of a capital market, for more sensible banking laws, and for a better monetary policy. Ortiz Mena keeps answering that the government has the responsibility for managing the private sector as well as the public sector; that the monetary authorities are doing their best to halt inflation; that the private sector is not carrying its weight; that everything possible is being done to develop a capital market; and that the government banks are doing a creditable job. Students of Latin American financial institutions will find many colorful and apt quotations in these volumes.

This synthetic dialogue mirrors the continuing argument between the private bankers and the government bankers in Mexico. Opinions as to who is winning the verbal battle will vary, but there is no doubt as to who is winning the real one: each year the public banking sector grows relatively larger.

Lagunilla's book is quite different. It is an expansion of the notes for the course on money markets and capital markets which he gives in the National University of Mexico. Seven of the eight chapters are crammed with terminology and statements about these markets in the rest of the world (not always accurate); the eighth deals with Mexico. This last, "The Mexican Finance Market," will be of interest to readers looking for a bird's-eye view of Mexican financial institutions and their problems.

*Money and Capital Markets.* By ROLAND I. ROBINSON. New York: McGraw-Hill Book Co., 1964. Pp. ix, 371. \$8.50.

We have a considerable body of literature on the money and capital markets, and about the system of financial institutions related to these markets, but most of it deals with one or another segment or specialized function. Here, now, is a book that views the financial markets and related financial institutions as a unified system. The perspective in which Roland Robinson portrays the money and capital markets should not only aid the task of learning by students but even improve the perception of their teachers.

This is a textbook. The author set out to write an expository treatment of the financial markets; he has designed the contents and adapted the style to that end. He accepts the limitations of textbook writing. Although a leading researcher in the capital markets for many years, Robinson fights no battles over controversial issues and makes no pleas for particular points of view.

Organization of material is an especially difficult task in describing the financial markets. No matter where you begin, there is a great deal that needs to be said almost in the same breath for any of it to be accurate and adequate. Robinson solves the problem of organization about as well as it can be solved by beginning with the most general description of money and capital markets and moving consistently from the general to the particular.

The first group of chapters seeks to place the financial markets in their economic setting at the center of a system of saving and investment. Saving and investment are described first in economic terms and then in terms of the flow of funds through financial institutions. Then the financial markets emerge clearly as the mechanism whereby both institutions and individuals convert funds flows into investment in financial instruments.

Money markets are distinguished from capital markets mainly by the length of maturity of the instruments in which they deal. Robinson conceives the money markets as markets for short-term instruments, ranging in maturity from less than one day to not more than one year. Capital markets deal in equity securities and in obligations with maturities of more than one year. Intermediate maturities are sometimes regarded as money-market instruments, but Robinson thinks they belong to the capital markets because their yields are more closely allied to long-term than to short-term rates.

The section on money markets is a masterpiece both of exposition and of self-restraint on the part of the author. A great deal has been written about the operations of the Federal Reserve System in the money market and about the market for Treasury securities. It would have been very easy to fatten up this book by writing at length on credit policy, fiscal policy, and debt management. Instead Robinson points to the abundance of supplementary materials that are available without cost, or at low cost, and limits himself to three chapters. This brief section establishes the main outlines and leaves to students and teachers the use of supplementary materials to fill in.

The discussion of capital markets is longer, partly because the author adopts a rather broad definition of capital markets. The stock and bond markets are described in three chapters, with separate chapters on the corporate

and municipal bond markets, and there are two chapters on less well-known segments of the market. The mortgage market, of course, has grown greatly in importance in recent years and clearly deserves inclusion in a study of capital markets. Justification for a chapter on consumer credit is not so clear because there is no open market for consumer-credit instruments, but there is a market for instruments issued by institutions that supply consumer credit, and it is to the demands on the money and capital markets by these institutions that this chapter is addressed.

The purpose of describing the financial markets is to provide a basis for analysis. In the fourth part of the book the author turns directly to analysis and offers five chapters on the dynamics of money and capital markets. There is a discussion of cyclical instability in the money and capital markets, followed by one on the problem of forecasting changes in rates and prices. These are conventional topics, but the next two chapters deal with topics seldom mentioned and rarely considered in any depth in the literature of the financial markets. One is on competition in the markets and the other describes evolutionary changes in the markets. These chapters are well worth reading even by people who consider themselves knowledgeable about financial markets.

The appraisal of Robinson's book by this reviewer is so favorable that it is hard to maintain a pose of critical sophistication. There are some things to find fault with. The market for U.S. government securities of all kinds is discussed under the general heading, "The Money Market," which is inconsistent with the proposition that only very short maturities of Treasury securities belong in the money market. The chapter on evolutionary change in the capital markets indicates only incidentally the great change in recent years in the role of financial intermediaries in the market for corporate equities. A book published in 1964 should not include a statement that new issues of Treasury securities are not formally underwritten, in view of the offering of two new Treasury issues for competitive bidding in the early part of 1963.

But the faults are of small magnitude relative to the merits. Perhaps the best quality of this book as a textbook for undergraduate use is that it is very well written. Sentences are short and lucid. Organization is excellent, despite the necessity for some repetition. Concepts are clearly developed and there are no needless displays of erudition to befuddle students. In truth the evidence of Robinson's scholarship is his ability to reduce complex concepts to their fundamentals and to describe them simply.

The other great merit of the book is that it presents such a clear view of the structure of the financial markets and provides such excellent orientation of the markets to the system of saving and investment. These qualities are very important in a text for students at a relatively elementary level of study. With this book they should neither bog down in abstractions of economic theory nor become lost in a maze of technicalities about the operation of markets.

Forecasting is always hazardous, but there is reason to think that this book will have a favorable influence upon the development of undergraduate curricula in business and economics. It provides a basis for a course concerned mainly with understanding of financial markets, rather than mainly with is-

sues of public policy in the area of money and credit. Such a course would be an excellent supplement to the conventional money and banking course in economics departments. In business schools it might plug the curricular gap that permits many students to emerge with degrees in business, but with little knowledge of the market system for financing business.

*Taxation of Foreign Investment Income—An Economic Analysis.* By PEGGY BREWER RICHMAN. Baltimore: The Johns Hopkins Press, 1963. Pp. ix, 140. \$5.50.

This slender but weighty book repairs much of economists' relative neglect of the theoretical effects of alternative tax policies for foreign-source income. The United States is the largest supplier of foreign investment funds, and its foreign capital stock is about half the world total. Effects of national tax systems and tax differentials on international capital movements become of increasing importance with rising mobility of funds and closer integration of national economies. To a considerable extent U.S. tax policy has reflected the view that any foreign investment has net advantages to the investing country and to national influence and prestige. Several tax provisions are favorable for income derived from investments abroad, including a foreign tax credit, deferral of tax until income earned by foreign subsidiaries of U.S. corporations is repatriated, and reduced tax rates for Western Hemisphere Trade Corporations. In recent years tax-sparing treaties have been negotiated, but not ratified, with several underdeveloped countries which give tax exemptions or rate reductions to attract private investment from the United States.

With recent balance-of-payments difficulties, the Administration in 1961 recommended tightening of the tax treatment of foreign investment income and elimination of tax deferral for retained profits of U.S.-controlled foreign corporations in the developed countries. The Congress enacted several major changes, the first in some twenty years, that lessened the favorable tax treatment of foreign investment, including a "grossing up" of foreign taxes and income in computing U.S. tax liability and tax credit, the taxation as ordinary income of capital gains arising from the liquidation of reinvested foreign earnings, and limitations on tax deferral where tax-haven and avoidance operations were most often involved. But Congress was unwilling to accept the broad recommendations for disallowal of tax deferral in foreign subsidiary operations in the developed countries. The form of tax treatment that will best serve the general interests of the United States and world-wide economic efficiency remains controversial. While conflicting views have been presented to the Congressional tax committees, comparatively little independent theoretical and empirical work has been done on these issues.

This book, begun as a doctoral dissertation at Johns Hopkins, is a creditable extension of Richard Musgrave's *The Theory of Public Finance* into the

international tax area. The primary, almost exclusive, concern is with the taxing of foreign-source income, particularly under the corporate income tax, and with the economic effects of capital flows as influenced by alternative sets of tax policies. No detailed consideration is given to legal, administrative, and accounting complexities.

At the beginning Peggy Richman systematically examines the criteria and principles by which tax policies for foreign investment income may be judged and reconciled with the varying tax claims of overlapping national jurisdictions. Concepts of tax neutrality and equity become more complex at the international level. Neutrality, for example, may be viewed with respect to all investors of one country so that tax considerations do not influence decisions to invest at home or abroad—capital-export neutrality. Or neutrality may be regarded as subjecting all who invest in one particular country to the same tax treatment—capital-import neutrality. Neutrality may relate not only to the places of investment, but also to tax effects on the residence of shareholders, location of management, place of incorporation, or forms of business organization, and these effects may be of considerable importance in decisions affecting the international distribution of tax base. What a capital-exporting country regards as equitable treatment in taxing the foreign-source income of its investors will vary, depending upon whether foreign taxes paid are regarded as part of taxable income, costs of earning the income, or full offsets against its own taxes. In addition, international equity involves a fair division of the tax revenue from foreign investment between capital-exporting and -importing countries.

No single policy can meet all of the desirable objectives of neutrality and equity. There is no generally accepted international principle to tax either by source of income or by residence of investor, and in practice a variety of policies is in effect in different countries. Mrs. Richman classifies and analyzes alternative tax systems to show how they serve various economic and equity objectives. The maximization of world welfare calls for capital being invested where the real rate of return is highest and argues for capital-export neutrality. Preference is given to the equity concept of total tax burden, so that the aggregate of taxes paid to both domestic and foreign governments is equalized for all investors receiving equal income from whatever source. International divisions of tax bases are analyzed through the development of an economic model involving a capital-export and a capital-import country with assumed identical production functions for capital and labor. Capital transfers in a perfectly competitive market are assumed to equate real rates of return to capital. In this setting different systems of taxing earnings from foreign-owned capital are shown to produce marked changes in national incomes and in distributions of corporate and personal income tax bases. The export of capital is likely to have adverse effects on the income of complementary factors, while gains to capital may be substantially reduced by the profits taxes of the capital-importing country. The analysis leads to the conclusion that the best general policy for the treatment of foreign-source business income, judged by both criteria of equitable distribution of tax base and investment neutrality, would

be a system of taxing both by source of incomes and by domicile of the investor, with a foreign tax credit but no deferral of tax on retained earnings.

The relative strength of various tax incentives to foreign investment are then examined by comparing the after-tax rate of return for the investor or reinvestor under each tax system, by considering whether he invests or reinvests in his own or the foreign country and whether the foreign investor is to measure his net after-tax income at home or abroad. Consideration is given to tax concessions which deliberately depart from tax neutrality with the objective of stimulating private investment from the United States in the underdeveloped regions of the world and also to tax concessions which appear to result in misallocation of capital among the high-income countries.

Influences on the balance of payments of the participating countries are also explored with a view to the tax effects on initial outflows of private investment, on the volume of after-tax earnings available in the capital-importing country for repatriation or reinvestment abroad, and on investors' decisions to remit earnings or retain them abroad. In each case the effects are analyzed by use of two-country models and consideration of the adjustments involved in reaching equilibrium under different assumptions. Basic relationships are expressed in algebraic terms, and then hypothetical though plausible values are assigned to respective terms to enable a numerical comparison of the indicated effects of alternative tax policies.

The final chapter utilizes Department of Commerce data to sketch the size and distribution of U.S. private foreign direct investments, the net outflow of new funds and reinvested profits for a dozen recent years up to 1961, and the foreign taxes paid by U.S. direct investment abroad for 1957. A comparison of private yields of investments made abroad and at home indicates that in most industrial categories foreign investment has been more profitable to the U.S. investor, and tax differentials appear to have been a rather small factor in the attractiveness of foreign investment. But comparisons of gross domestic yields with foreign net yields, to compare national returns from the relative investments, indicate that only in agriculture and petroleum production has it been nationally more productive for the United States to invest abroad.

The author makes a plea for a more neutral system, consistent not only with world welfare conditions but also with the national interest of capital-supplying countries in retaining a larger share of tax bases. These considerations plus the somewhat precarious current balance of payments of the United States lead again to the suggestion of ending tax deferral with respect to investment in high-income countries and also to a modified foreign tax credit that would allow offset of only up to one-half of the full U.S. tax liability on foreign-source income.

The main virtues of the study are in its theoretical analyses of tax effects on capital flows. Only brief allusions are made to indirect effects upon international trade that may be induced by the foreign investment and to the questions of whether these trade effects may or may not be of an equilibrating character. Mrs. Richman readily acknowledges the need for more detailed and

refined empirical work and for intensive consideration of the effects of foreign investment on the pattern of international trade.

*Taxation and Economic Development in Tropical Africa.* By JOHN F. DUE. Cambridge: Massachusetts Institute of Technology Press, 1963. Pp. 172. \$6.00.

With growing interest in Africa, in taxation, and in economic development, the publication of this book is a welcome addition to the limited materials available to scholars in this field. The book is based on a series of lectures given by the author during December 3-7, 1962, at Cambridge, under the auspices of the Harvard Law School's International Program in Taxation and the M.I.T. School of Industrial Management. It is based in part on four months of field work in 1962 when Professor Due interviewed officials in the Ministries of Finance, Local Government, and Economic Development in eight African countries (Sierra Leone, Ghana, Nigeria, Kenya, Uganda, Tanganyika, Zanzibar, and Rhodesia).

Although the role of tax policy in relation to economic development is examined in the ninth and last chapter, the major emphasis of the book is on tax structure, the use of various taxes, and such problems as that of collecting taxes; these are dealt with in seven chapters after an introductory chapter on the economic position of the eight countries and their main problems of economic growth. Selected references at the end of each chapter and a valuable index will enable researchers to use the study as a reference for special questions, such as double taxation of dividend income and allowances and exemptions for personal income tax, and for specific information on a particular country.

The tax structure in the eight African countries covered in the book is not very much different from that of most underdeveloped countries with a per capita income of less than \$200 per annum. Thus, the total tax revenue collected in these countries in relation to gross domestic product in 1960-61 varied from 9 per cent in Tanganyika to 17 per cent in Zanzibar (p. 26), while in a larger sample of underdeveloped countries it varied from 8 per cent in India to 24 per cent in the United Arab Republic, with a median of 13.7 per cent (see article by the reviewer on "Taxation Problems and Policies of Underdeveloped Countries" in *IMF Staff Papers*, November 1962). The great dependence on indirect taxes as a source of revenue in these African countries is also similar to the position in most underdeveloped countries (about two-thirds to three-fourths of total revenue originating from indirect taxes) except Rhodesia, where direct taxes account for 67 per cent of total tax revenue which approximates the relationship in the more-developed countries. Kenya has also succeeded in collecting a large percentage of total revenue (44 per cent) in the form of direct taxes.

There are two interesting features in the direct tax system in these African

countries. Firstly, with the exception of the tax in Southern Rhodesia, all income taxes were originally based upon the Colonial Model Income Tax Ordinance prepared in 1922 and, despite subsequent modifications, the U.K. case law and tax guides are applicable to a substantial extent in these countries. The other feature relates to direct personal taxes: with the exception of Zanzibar, these African countries have developed a very simplified form of direct personal tax which is in a sense hybrid between a poll tax and an elementary form of income tax (pp. 61-62). The poll tax is not uncommon in other underdeveloped countries, but in the African countries there is a limited degree of graduation because the amounts are fixed in relation to income brackets.

The author reviews the difficulties of levying direct taxes that are common to most underdeveloped countries, including administrative organization and procedures used for collection (pp. 51-56). While the author states that "it is very difficult to evaluate the over-all efficiency of income tax administration in these countries" (p. 56), there is undoubtedly a lack of trained personnel and too few tax-collecting inspectors, especially in West African countries (e.g., Ghana, where the degree of Africanization has been complete). The trend toward Africanization in East Africa is likely to proceed at a rapid pace in the future. Their system, unlike that of the United States, and following the British tradition, does not permit the taxpayer to calculate his own tax, this being done by the assessing officer. For cases where it is difficult to assess incomes, such as those for traders, the 1961 Ghanaian income tax law provides the method of presumptive income, i.e., the income tax authorities presume the figure of taxable income to be not less than a certain amount, e.g.,  $2\frac{1}{2}$  per cent of gross turnover for traders.

Most underdeveloped countries would like to mechanize record keeping by using data-processing equipment, but these countries have not rushed into using the latest devices. The Sierra Leone Administration quite rightly believed the use of mechanization to be unwarranted at present. Governments can raise more revenue by tightening collecting machinery through simple enforcement measures and giving adequate rewards to tax collecting officers than through mechanization of record keeping.

A number of details are presented on the exemption given to newly established industries either directly or through lower customs duties on equipment (pp. 35, 86, 153-54), and Due mentions the administrative difficulties experienced in Ghana and Nigeria in using the tax-holiday type of legislation. However, he does not conclusively state whether even the tax-incentive types that he prefers, namely accelerated depreciation allowances and the provision for loss carry-forward, have been instrumental in promoting industrialization and economic development.

The indirect taxes covered are customs, excise, and export duties, but the space devoted to indirect taxes is much less than the amount warranted by their importance. While customs duties are dealt with adequately, very little information is given on taxes on motor fuels, for example, and the uses made of such receipts. The collection of indirect taxes is also hampered by lack of trained personnel and encounters enforcement difficulties. On customs duties

he concludes that "all developing countries that rely heavily on customs must look forward to the future, when, with foreign trade constituting a constantly declining portion of national income, other tax resources must be developed" (p. 159), which to the reviewer is not self-evident. Undoubtedly, there is need to develop other sources of revenue than customs because such revenues are subject to cyclical variations, and not because there will be a long-term decline in the importance of foreign trade. In some countries foreign trade has become more important with development, while in others it has become less important. There is no necessary correlation between growth and relative importance of trade that merely depends on the type of development.

The author, in the discussion of direct taxes versus indirect taxes (pp. 147-51, 156-58), points out the usual advantages and disadvantages without taking a definite position between the two. But the present reviewer feels that African and other underdeveloped countries should attempt to develop direct taxes only as a long-run objective and should concentrate on collecting revenue by the easier method of indirect taxes because the advantages of equity and stability of direct taxes are outweighed by the major problem of trying to obtain noninflationary sources of government finance to avoid deficit financing. Lastly, Due's discussion of the important tax device of marketing boards, as in Ghana, is very limited, and despite the disadvantages of such devices, the revenue-yielding aspects have generally been understressed by its critics.

*Public School Finance—Economics & Politics.* By JESSE BURKHEAD WITH B. M. GROSS AND C. S. BENSON. Syracuse: Syracuse University Press, 1964. Pp. xii, 394. \$8.75.

"It is the theme of this volume that the resources for a more adequate support of public education are available; the task is to mobilize these resources and to utilize them effectively" (p. 359). To accomplish this task, the author hopes for organizational innovation, both within the school systems and, externally, at all levels of government. Many suggestions are made, for example: school boards should increase citizen involvement, chief state school officers will have to immerse themselves in the political process of public resource allocation, federal agencies should collaborate with each other and coordinate with state and local educational agencies and above all stimulate the states (pp. 363-64).

The audience for which this book was intended presumably covers a wide range of persons professionally concerned with the support of public education. Each reader will be familiar with some of the topics. The specialist in public finance will recognize recurrent quests: the attempt to measure the benefits of educational expenditures, the search for the optimum method of dividing these expenditures among the three levels of government, the groping for better formulas for state and federal aid, the pursuit of ways to improve or find alternatives to the property tax. The political scientist will have

studied the tensions impeding federal aid—race, religion, localism, urban-rural rivalries, and control of the educational apparatus. The sociologist will have tried to unravel the complex of ills that beset the depressed areas of our large cities. The historian will know the halting course of federal aid to education from its wellspring in 1787. The school administrator will be all too aware of the special demands of his job, the necessity to provide an intangible and complex output for clients with whom he must come into unusually close contact.

As an economist, I liked best a report (Chapter 3) of empirical research on the determinants of school expenditures. Four dependent variables (total and local expenditures, each per capita and per pupil) for selected school systems in 23 states were used in least-squares multiple regressions. With 20 independent variables, the results were profuse, although none of the coefficients of multiple correlation was high. By comparing the coefficients for total and for local expenditures, it was possible to discern the effects of state and federal aid. As might be expected, total expenditures tend to vary with cost while local expenditures reflect community income levels. I also enjoyed three chapters (12-14) which describe the work of the Physical Science Study Committee, the government's experience in administering the National Defense Education Act, and the aid given to federally affected schools.

As a taxpaying parent, I was cheered to learn that there are avenues for improvement in addition to mobilizing my checkbook. Almost *any* experiment in teaching technique seems to push students ahead because of the "strong interest-enthusiasm factor" (p. 89). The quality of instruction may be improved by team teaching and by altering the technology of education, which has hardly changed since 1890 (p. 80 ff.).

As an aging scholar, I fuss about finding the footnotes in a block at the end. Anyone who reads this sort of compendium wants *instant* footnotes! My other comment is also captious. Perhaps I have merely failed to adjust to the new entrepreneurial style of research, but I still feel that it fosters dutiful—and, hence, inert—exposition; lonely thinkers are more likely to impart life and purpose to their thoughts. This book is really the work of 18 men, who in turn acknowledge the help of a host of others. Two chapters were "specifically commissioned for this volume."<sup>1</sup> Eleven of the chapters are summaries by Jesse Burkhead of monographs published by the Syracuse University Press as "The Economics and Politics of Public Education Series." This leaves the first and last chapter as fresh territory for the author, but only in the last few pages does he seem to get free from the task of trying to blend an interdisciplinary seminar into a point of view. Too many minds can spoil the flavor of research. I fancy that this book would have been more provocative if each monographer had distilled his own work. What I *really* long for is the lifework of some dogged schoolman who has neglected a despairing wife and three wan children to prove to the nation that public education should not be stinted.

*Public Finance—An Introduction to the Study of the Public Economy.* By ANSEL M. SHARP AND BERNARD F. SLIGER. Homewood, Ill.: The Dorsey Press, 1964. Pp. xiii, 411. \$7.50.

I teach a junior-senior-level course in public finance for students majoring in economics, most of whom are not likely to do graduate work in the subject. Working within the context of a liberal education, I conceive the major objective of such a course to be teaching the students to think intelligently about the economic aspects of certain public issues. For a text to be adequate for this course, it must apply the tools of economic analysis to the major problems of concern to public finance: allocation of resources between the public and private sectors of the economy and within the public sector; division of the burden of government support; effect of government activity on the private economy; and problems of stabilization. Ancillary issues which should also be covered briefly are: the burden of the debt, the techniques of budgeting, and the particular fiscal problems of a federal system.

On my shelves are eight textbooks published or revised since 1959, all of which indicate in the preface that they have been written for courses like mine. Each of these books considers all of the major issues listed above, but there is a decided imbalance in presentation. Just short of half the pages (47 per cent) on the average are devoted to the discussion of government revenues. Student interest, importance, or complexity cannot justify this much attention being given to this one aspect of public finance. Much of the material presented on taxes is historical and institutional, with most of the analysis being confined to a partial-equilibrium examination of particular taxes. At best this type of analysis is a demonstration of a useful tool; frequently it is dull and inconclusive; and at its worst it is misleading and misdirected. What are we able to say on the effect of a particular tax on work effort; risk acceptance, saving, price, output, etc.: only that our theoretical analysis is inconclusive and our empirical evidence almost nonexistent. Certainly we should show students these tools but not belabor our poverty.

Concentration on taxes means that the other problems of public finance get short shrift. Only 14 per cent of the pages in the same eight texts were devoted to fiscal problems and only 12 per cent to the question of allocation. Perhaps the brief coverage of compensatory finance can be justified, since most colleges do offer a separate course in macroeconomics in which policy is covered. But the question of allocating resources between the public and private and within the public sector does deserve more attention. Ansel Sharp and Bernard Sliger say: "One of the very few topics on a college campus that can compete with football for student interest is taxes" (p. 193). Perhaps so, but I have never heard students discussing the effects of the income tax on the labor-leisure choice. My students argue about the size of the government sector, the propriety of Medicare, federal aid to education, the authoritarian nature of social security; in other words, the allocation of resources. Unfortunately, instead of exploring the basis for these controversies, most texts give little more than a historical elaboration of the growth of particular components of the public budget.

The over-all balance of the Sharp and Sliger book is better than most.

While the tax analysis suffers from the failings mentioned above, their presentation has the advantage of being short—only 30 per cent rather than half the book is devoted to public revenues. Furthermore they do give some consideration to the allocation problem. Unfortunately they suggest that the resolution is simple: "It follows, then, that the distribution of resources between public and private use should be carried to the point where the last unit of a resource used by the public adds the same to social welfare as it does to social cost, for, in this case, total welfare of society is maximized" (p. 18). However, they recognize that this principle is not used in practice: "Two reasons are: many public officials are unaware of the principle of equating marginal social benefit and marginal social cost; two, application of the principle implies that reasonably close estimates of social benefits and cost can be made" (p. 18). The immediately following paragraph starts: "The difficult problem of estimating social benefits and social costs, in some instances, is not insurmountable" (p. 19), and goes on to give an 18-line description of cost-benefit analysis. Nothing is said of the dubious nature of community indifference curves, or, except for the quote above, the impossibility, in most cases, of establishing the location of social indifference curves. It seems to me misleading to leave students with the impression that the disagreements over public policy could frequently be resolved were it not for the ignorance of simple economics on the part of our lawmakers. Even Senator Douglas may have difficulty applying their dictum.

The one rather different feature of this book is the amount of space devoted to the examination of four specific programs: education, highways, social security, and city government. Again it is unfortunate that the authors do not take this opportunity to explore the complexities of the allocation problem except with regard to roads. For education it is solved by fiat: "This coefficient [an income elasticity of one] reveals that people will have to place different values on education, or that government will have to be more arbitrary in its handling of school finance if the nation is to have adequate—or—better school facilities in the future" (p. 343). Students are gullible; authors of texts have a duty to make explicit what are only value judgments.

The failings enumerated above are common to most texts on public finance. For a course such as mine this is as good a book as any I have seen. It is well written, easily understood, and the presentation is a useful balance of theoretical and institutional material. It deserves consideration for classroom adoption.

*Industrial Growth and World Trade—An Empirical Study of Trends in Production, Consumption and Trade in Manufactures from 1899-1959 with a Discussion of Probable Future Trends.* By ALFRED MAIZELS. New York: Cambridge University Press, 1963. Pp. xxiii, 563. \$14.00.

In this voluminous work, Alfred Maizels attempts a comprehensive explanation of the effects of industrial growth on the pattern of world trade in

manufactured goods over the past 60 years. For both its statistical coverage and analytical quality, this should rank as one of the leading studies of the past decade in the field of international trade.

Maizels has two central themes. The first is the relationship between industrial growth in the developing countries and the structure of their foreign trade. The second is the changing set of trade relations among the established industrial countries. The main feature of the latter is the decline of Britain as the dominant exporter of manufactured goods since the beginning of the century. These two analyses are skillfully interwoven to provide an over-all explanation of the changing patterns of production and trade in manufactured goods.

The last study of similar scope was Hilgerdt's classic *Industrialization and Foreign Trade*, published in 1945. Maizels extends Hilgerdt's empirical base to include a much larger coverage of less developed countries and adds another dimension to the analysis by subdividing manufactured goods into 12 categories. Hilgerdt's principal conclusion—that the trade-reducing effects of industrialization are far outweighed by the expansion of total demand for manufactured goods—is amply supported and extended in the new study.

Maizels makes a major empirical contribution by constructing trade matrices of the exports of 12 categories of manufactured goods from principal suppliers which account for 90 per cent of world exports. To the extent possible, these are compiled for 47 countries of destination and cover seven selected years between 1899 and 1959. The countries of destination are chosen to give fairly equal coverage to three types of economy: (i) advanced industrial countries; (ii) countries in process of industrialization; (iii) nonindustrial (primary-producing) countries.

Changes in the volume and composition of world trade in manufactures are traced to demand factors (indicated by the rise in each country's GNP and total consumption of each commodity group) and changes in supply conditions (indicated by variations in suppliers' shares of markets and their relative export prices). While these variables are never put together in a formal model, they are used fairly systematically to link up the growth in total demand for the several categories of manufactured goods, the rise in the share of their internal demand that is supplied by the industrializing countries, and the changing shares of exports in each category provided by the principal suppliers. As a by-product of this comprehensive analysis, Maizels is able to describe the typical growth and trade patterns of each of his three groups of countries and to study the changing pattern of trade in each major commodity group separately.

Much of Maizels' explanation of the observed changes in demand and supply consists of listing contributory factors on a fairly intuitive basis. Some of his most interesting pieces of analysis, however, are those in which he attempts a more formal test of alternative hypotheses by the use of multiple regression analysis. Among the most useful conclusions reached on this basis are:

1. The demonstration in Chapter 2 of the similarities and differences between cross-country patterns of growth in manufacturing and patterns derived from time-series for ten countries.

2. The demonstration in Chapter 5 that the differences in export performance of the developing countries have stemmed mainly from differences in demand for their principal exports, with no evidence of a general reduction due to supply limitations (although there are some notable individual examples).

3. The relations among rise in levels of income, the degree of import substitution, relative prices and net demand for manufactured imports (Chapter 6). Inter-country analysis shows that the rise in consumption of manufactured goods outweighs the effects of import substitution and typically leads to a rise in manufactured imports. An analysis of individual countries over time shows only a few exceptions—notably Argentina, India, and the United Kingdom—to this general conclusion.

The major faults of this otherwise admirable study are its loose organization and somewhat erratic methodology. Maizels' failure to set out a general model or to analyze the relations between the variables which he can observe and the underlying explanatory variables makes it more difficult to assess his results. It would be useful to know, for example, whether an alternative grouping of countries would give significantly different results, since this critical assumption is made without a very convincing justification. Offsetting this methodological weakness, however, is a good sense of what is empirically relevant and "feel" for the data.

Since international trade is the net result of a large number of factors affecting the internal workings of each economy, it is probably inherent in the subject matter that an empirical study should turn out to be large, repetitious, and difficult to sum up in simple terms. Much of Maizels' analysis is admirably clear, but he sometimes appears to be the prisoner of his multi-year trade matrices, which almost force him to produce many more analyses and tables than the reader can readily digest. It would be most unfortunate, however, if the occasional tedious going should limit the understanding and dissemination of Maizels' principal conclusions. There is a wealth of source material and insights here for policy-makers concerned with development in both the advanced and the less developed countries.

*The Politics and Economics of European Integration—Britain, Europe, and the United States.* Rev. ed. By U. W. KITZINGER. New York and London: Frederick A. Praeger, 1963. Pp. 246. \$5.50; paper, \$2.25.

No book that I have read provides as clear and concise an account of the origins and postwar development of the European integration movement as Kitinger's brief volume. This is no plodding chronology of events and recital of treaty provisions, but a lively and perceptive account of the dynamics of the integration process written by one who is obviously moved by a deep personal commitment to the supranational idea. U. W. Kitinger, Fellow at Nuffield College, Oxford, was for six years an economist with the Council of Europe, a body which, ever since its establishment in Strasbourg in 1949, has

served as a high-level forum and stimulator of new steps in the movement for a united Europe.

The first half of the book consists of four closely related chapters: a historical summary of the main forces behind the movement toward European unity; a brief exposition of the economic provisions of the three treaties and an account of how they had been carried out in practice until approximately mid-1962; an examination of the institutions and political implications of the treaties; and a discussion of the association of African countries with the Community. None of these matters is treated in any great depth, but Kitzinger does have a sharp eye for the highlights of his subject.

If one were to describe a dominant theme running through these chapters and indeed throughout the book, it would relate to the self-generating character of the integration process, once the movement gets under way, on the basis of a core of precise and irrevocable commitments. Each move toward freer intra-Community trade, for example, not only expands opportunities but also creates problems (e.g., the need for tax harmonization) which, on the assumption of no backsliding, can only be solved through new regional initiatives in other spheres. In this process a deeper community of interests is consolidated and a new plateau is established from which regional solutions are again sought to new problems. In projecting this dialectic, the author sees the Community institutions as playing a key role. The dedicated Europeans in these bodies exploit tactical situations in order to advance Community solutions to rectify the imbalances caused by partial integration. In Kitzinger's view, "a thoroughgoing community of economic interests will lead more and more to a political community of interests: and then a Political Community may not be far off."

Although there is a great deal of substance to the slippery-slope thesis of European integration, two caveats should be entered. First, as the author himself recognizes, progress is conditioned on political will and support. Despite the internal dynamics of the integration process, a De Gaulle can slow it down or stop it at any point beyond the precise but sharply circumscribed commitments of the treaties; and somehow Europe could learn to live with its problems and contradictions. Second, outside the commercial policy field, some of the key issues facing the members of the Common Market do not naturally lend themselves to solutions on a Community scale but rather on a world-wide or industrial-country basis. The Group of Ten rather than the Six is the more logical body within which to develop reforms of the international monetary system; Working Party 3 of the OECD is a natural place in which to deal with the policy implications of imbalances in the over-all payments positions of EEC member countries; and the Development Assistance Committee rather than some EEC institution would appear to be the most effective forum within which to coordinate bilateral aid policies toward less developed countries. To be sure, the EEC does try to develop a common point of view on these matters, but the inherent pressures for a Community policy are weaker where rational solutions require action on a world-wide scale.

According to the publisher, the present volume is a revised and expanded

edition of a book previously published in Great Britain under the title *The Challenge of the Common Market*. Not having read the earlier edition, this reviewer cannot comment on the changes or additions included in *The Politics and Economics of European Integration*. In the present version, all of the second half of the book deals with Britain's relationship to the Common Market, starting with the Europe-wide free-trade-area negotiations which collapsed in 1958, and ending with the abrupt rejection early in 1963 of Britain's application to join the Community. With profound sympathy and understanding for the United Kingdom's predicament, the author carries us through the soul-searching that led to the historic British decision to end its separation from Europe and reviews the main issues in the detailed negotiations with the Community in 1961-62.

In the light of all the attention devoted to the British-European relationship and the absence of any separate treatment of U.S. policy toward the unity of Europe, one cannot but feel that the book's subtitle, *Britain, Europe, and the United States*, is a misnomer. So much mystique surrounds the recent concepts of community and partnership in the Atlantic area, that a real service would have been rendered by including a comparable analysis of the evolving U.S. conception of its relationship to Europe.

In his last chapter Kitzinger tries to assess the implications of the French veto of British membership in the EEC. Here the author takes off into space and finds a cloud with a bright silver lining. He recognizes that the major issues of our time transcend both national and regional solutions and sees in this fact the basis for a new role for Britain. In attacking such problems as commodity arrangements and "world development plans," the United Kingdom would take the lead in building a network of "functionally oriented, democratically controlled and geographically interlocking institutions as the basis . . . of a higher, more civilized, even perhaps a more democratically responsible world order." In working toward this goal, the United Kingdom would take several leaves from the Common Market book, since the EEC has after all pioneered a new approach to transcending national interests. Kitzinger provides no blueprint for his soaring idealism, no clue as to the nature of the solutions for which a new institutional structure is needed. One wonders, therefore, whether his cosmic chariot has not been put before its team of horses.

*World Monetary Reform: Plans and Issues*. Edited by HERBERT G. GRUBEL. Stanford: Stanford University Press, 1963. Pp. xiii, 446. \$10.00.

Perhaps I should have disqualified myself as a reviewer of this volume, since I am one of the authors of the writings collected. But being only one of 22 authors, I do not think the conflict of interest is serious.

The purpose of the volume is to bring together the major contributions to the discussion of world monetary reform; to let the authors and the critics of the various reform plans speak in their own words; and thus to let the student find the most representative quotations on the subject within the covers of a single volume. The editor modestly confines himself to the task of selecting

the papers, articles, testimonies, and abstracts, and of contributing a competent introduction, only 11 pages long.

Part I, "Centralization of International Reserves," contains a 40-page condensation of Triffin's book (published in 1960); Keynes' "Proposals for an International Clearing Union" (1943); the "Stamp Plan—1962 Version"; Angell's *EJ.* article (1961); and four critiques of the Triffin Plan, by Harrod, Altman, David Rockefeller, and Leland Yeager (all published in 1961).

Part II, "Improvement of the Gold Exchange Standard System," contains one of Bernstein's statements prepared for Congressional hearings (1962); a condensed fusion of two articles by Harrod (1961 and 1962); the English version of an article by Per Jacobsson (published in French in 1962); Lutz's Princeton essay on the multiple-currency standard (1963); a brief statement by Machlup prepared for Congressional hearings (1962); one of Roosa's articles (1962); one by Wallich (1961); and a piece excerpted from Zolotas' writings (1961 and 1962).

Part III, "Flexible Exchange Rates and Return to the Gold Standard," includes the revised version which the Joint Economic Committee published of Meade's article from the *Three Banks Review* (1961); Rueff's plea for a return to the full gold standard (1961); Heilperin's endorsement of this plea (1962); a review article by Balogh (1960); a not easily available survey by Harry Johnson (1962); a panel discussion before Congressman Reuss by Bernstein, Harry Johnson, and Machlup (1962); the chapter, slightly condensed, on "Recommendations" from the Brookings Committee Report, for which Walter Salant is chiefly responsible (1963); and finally another article by Triffin (1961).

If Grubel's collection had appeared one year later, it might have included the newest crop of plans, such as the Posthuma Plan (1963), the Kaldor Plan (1964), and the newest Bernstein Plan (1963-64). But, although "Of making many books there is no end," there must be an end of making one book. Every anthology must have a cut-off date, and Grubel's collection is unquestionably as representative of the present-day discussion as one may ask.

Experts in the field will appreciate this volume as a convenient reference book; teachers in monetary economics and in international economics will be glad to have this time-saving aid in the preparation of their reading lists; students will prefer to find so many assigned writings within the covers of a single volume; and librarians will delight in being saved the trouble of putting 20 different volumes of journals and public documents on their reserved-book shelves.

*Quantitative Decision Procedures in Management and Economics—Deterministic Theory and Applications.* By C. R. CARR AND C. W. HOWE.  
New York: McGraw-Hill Book Co., 1964. Pp. xv, 383. \$8.95.

This book is intended for use in a one-semester course in quantitative meth-

ods for students with little mathematical background (some understanding of calculus is assumed, however). The entire work is devoted to a study of deterministic optimization problems. A forthcoming work will deal with stochastic decision problems.

The current work is divided into three sections. The first, consisting of 121 pages, deals with the optimization of a function of a single real variable. It attempts to give some notion of what is involved in constructing a mathematical model and what is meant by an optimization problem. It also gives definitions pertaining to functions, continuity, derivatives, sets, etc. The section begins and ends with a discussion of the simple lot-size model of inventory theory. The second section, consisting of 149 pages, treats optimization problems involving a finite number of variables. The main topic covered here is the simplex method of linear programming along with an introduction to duality and parametric programming (no discussion of the transportation method is given). Also, brief discussions of the Kuhn-Tucker conditions and quadratic programming are provided as well as a somewhat more extensive discussion of all integer linear programming. A brief treatment of vectors and matrices is to be found in an appendix to the chapter on linear programming. The third section of 100 pages continues the study of optimization problems involving several variables, and introduces the notion of step-wise maximization that is so important in dynamic programming. A discussion of dynamic programming, which is restricted mainly to showing how the recurrent relations can be solved analytically in certain simple cases, is included. The text ends with an additional discussion of the lot-size model. Problems for solution are to be found at the end of most sections.

The authors' objectives are to provide a text that familiarizes the student with the "mathematical way of thinking" and which also develops sufficient competence to use the techniques studied. The task of achieving these objectives in a one-semester course with students of limited mathematical background is a very difficult one. It is the reviewer's belief that this text is not completely successful in meeting these objectives. The fundamental reason for this is that the entire method of development seems inappropriate for the audience, even if one agrees that the material covered is precisely what should be covered. The authors have not chosen to develop the material from an elementary point of view, with a strong emphasis on giving the reader a good intuitive understanding of the subject, but have instead chosen an approach which is based on making use of a large number of advanced theorems that are simply quoted without proof. Only occasionally is some very elementary result proved, and when this is done, other unproved theorems are usually required in making the proof. A further unfortunate feature of this procedure is that often not enough theorems are quoted to cover all cases. For example, in the development of the simplex method, it is assumed that the set of feasible solutions is a convex polyhedron. Thus no mention is made of the fact that the rules developed break down if all  $x_i \leq 0$  for the vector to enter the basis (thus in reality indicating that there is an unbounded solution). Similarly, no discussion is given of the fact that degeneracy could cause problems (the authors claim that the objective function increases at each step in the

simplex method—something that cannot be guaranteed when degeneracy is present), but that in practice it doesn't. Neither is any theorem stated which guarantees that when all  $z_j - c_j \geq 0$ , one has an optimal solution (indeed the criteria for terminating the iterative procedure receives only a passing mention). Even something so important as the artificial variable technique for finding an initial basic feasible solution receives only a cursory description without any detailed example. Still another unfortunate feature of this approach is that rules are sometimes given without any indication whatever of why they are needed. An example of this occurs in the discussion of integer programming, where it is stated that the matrix of the coefficients must be converted to an all-integer matrix before starting the computational procedure. No mention is made as to why this is necessary (the reason is simply that all the constraints are assumed to be inequalities, and in order to guarantee that the slack variables will also be integers, the conversion must be made). The method of development thus makes the text something very close to a cookbook, even though one which appears very learned and lends somewhat of a touch of mystery to the subject.

The authors also chose to omit completely any discussion of the problems involved in numerical computations. This can indirectly give a number of seriously erroneous impressions. For example, in reading the text one gets the impression that it is just about as easy to solve integer programming problems as it is to solve linear ones. One case where the authors do make a reference to computations is very misleading, if not totally incorrect. They assert that the equivalence under certain conditions between saddle-point problems and optimization problems is important because one wants to convert a nonlinear programming problem to a saddle-point problem so that one can solve it efficiently using a gradient method (in reality, one would much prefer not to use the Lagrangian when applying a gradient method).

Finally, the text does very little to develop the student's ability to formulate mathematical models from real world situations. In the text the only example illustrating this is the simple lot-size model of inventory theory, and even though almost 50 pages are devoted to it, one never really gets a clear idea of what the model is or precisely what assumptions are being made. The discussion of this model never even reaches the stage of introducing the notion of a reorder point or indicating how to handle nonzero lead times.

Several other minor annoying features of the text which might be mentioned include the use of many abbreviations such as GMP (general maximum problem), GDP, BMP, BOP, etc., which make it read like a military-procedures manual, and the insertion of seemingly vacuous propositions (as the authors call them) at various points in the text, such as "Reality is a subject for philosophers, not scientists."

Because of the above considerations, the reviewer cannot provide a very enthusiastic endorsement of this work for the purpose that the authors have in mind. It would also seem to have only limited value as a reference work.

*Profitability and Size of Firm.* By H. O. STEKLER. Berkeley: Institute of Business and Economic Research, University of California, 1963. Pp. 112. \$2.50.

During the past 30 years, there have been a number of studies, by Epstein, Crum, Steindl, Osborn, and others, of the relationship between a firm's size and its profitability, the primary purpose being to obtain clues regarding economies of scale and to measure the likelihood that firms of various sizes can survive and expand. H. O. Stekler's monograph, prepared under the direction of Richard Holton and Joseph Garbarino, is the latest addition to this literature.

Using the data from the *Statistics of Income*, Stekler describes the relationship in all manufacturing and in each two-digit industry between firm size, measured by total assets, and profitability, measured in a variety of ways—before taxes, after taxes, with and without adjustments of officers' compensation, profits as a percentage of net worth, and profits plus interest as a percentage of total assets. The average relationships during 1947-54 and 1955-57 are presented in each case.

His principal findings are as follows: First, including all manufacturing firms (whether they made profits or losses), there is in most cases a tendency for the after-tax profit rate to increase with size of firm up to \$10-50 million in assets, but to decrease thereafter. Turning to individual two-digit industries, the size of firm, measured by assets, where the after-tax profit rate<sup>1</sup> in 1947-54 was highest was about \$1 million in printing, petroleum, and primary metals; \$5-50 million in apparel, furniture, and rubber; \$50-100 million in food, fabricated metals, machinery, and electrical machinery; and over \$100 million in the others.

Second, using the after-tax profit rate as a rough measure of the ability to expand, Stekler concludes that "the smaller firms [under \$250,000 in assets] as a group are able to survive, but their ability to expand is less than that of the larger firms. The largest firms can generally expand as fast as the remainder of the industry, indicating that no general decline in concentration can be expected" (p. 102).

Third, after applying Alexander's adjustment of officers' compensation, he compares the pretax relationship between size and profitability with the post-tax distribution and concludes that "the tax system probably does not handicap the *relative* expansionary ability of the smaller firms and may actually aid it. As for the larger firms, their ability to grow does not seem to improve" (p. 102).

Fourth, adjusting officers' compensation and excluding firms with losses, he finds an inverse relationship in most two-digit industries between profitability and size of firm. Moreover, including all firms, there is a tendency for

<sup>1</sup> Without any adjustment of officers' compensation and using profits as a percentage of net worth.

the interfirm variation in profit rates to be inversely related to size of firm, the standard deviation among the smallest firms (assets under \$25,000) being about ten times that among the largest firms (assets over \$250 million).

Turning to an evaluation of the book, it seems somewhat long on description and short on analysis. Unfortunately, Stekler makes little attempt to link his empirical findings in any precise manner with the important theoretical and policy questions in this area. He says that he knows of no way to use his empirical findings to estimate economies of scale; and he makes no attempt to explain the observed size-profitability relationships or to relate his findings to the recent attempts to construct econometric models to represent the process of firm growth. His discussion of the relationship between profits and the ability to expand seems somewhat casual.

In addition, I do not understand why Stekler believes that firms with losses should be omitted in Chapter 5, where he is concerned with "the relative ability of firms of different sizes to earn profits." It seems to me that the relationship between size and profitability among firms with positive profits is of little interest. Obviously, because of the inverse relationship between size and the variability of profits, there will generally be an inverse relationship between size and average profitability if one excludes firms with losses (so long as the average profitability of all firms does not rise too rapidly with firm size—which it usually doesn't).

Nonetheless, Stekler's findings should be of interest to many economists interested in industrial organization, and by providing another set of data regarding profitability and size of firm, it should help to stimulate further econometric work in this area.

*Studies in Process Analysis—Economy-Wide Production Capabilities.* Edited by ALAN S. MANNE AND HARVEY M. MARKOWITZ. Cowles Foundation Monograph 18. New York: John Wiley & Sons, Inc., 1963. Pp. 427. \$14.00.

Process analysis is a search for numerical estimates of the alternative physical outputs which a workshop, farm, industry, or entire economy is capable of producing over the course of time, given estimates of the relevant resource availabilities and the present state of the arts. A process-analysis model is ordinarily drawn up to include alternative known engineering or agricultural techniques that would be serious candidates for adoption under plausible changes in resource or demand constraints. Thus, at the expense of being much more arduous in initial set-up than input-output analysis, process analysis reintroduces into the disaggregated structural model some part of that substitutability among resources that is naïvely exaggerated in GNP projections, but that is clearly oversuppressed by the very act of disaggregation. Non-linear relationships within each technical process are allowed, where appropriate, but an attempt is made to keep the various processes independent and additive. The hope of the authors of these initial studies is that a stock of jigsaw-puzzle pieces will accumulate upon the shelf, each piece being a set of processes for a particular industrial or agricultural sector. The individual sec-

tor studies can then be combined into multisector models at incremental costs lower than the original outlays. When taken from the shelf for fitting into the larger pattern, the pieces will need to be more or less drastically reshaped in the light of newer engineering knowledge; but presumably "the updating of production coefficients (which should be done periodically for all models) is a much easier task, more subject to delegation and routine procedures, than is the original model-building."

The sectoral models brought together in this volume are studies of U.S. petroleum refining (A. S. Manne), U.S. petroleum transportation (T. A. Marschak), South American fertilizer production and plant location (T. Vietorisz and A. S. Manne), the spatial pattern of U.S. grain production (E. O. Heady and A. C. Egbert), iron and steel production (T. Fabian), and metal-working shop activities (H. M. Markowitz and A. J. Rowe). The book culminates in a ten-year investment-planning model of a number of key industrial sectors of the Mexican economy (A. S. Manne), which shows the kind of results that can be obtained in one summer, with a total expenditure of less than one man-year, when some of the industries have already been characterized through individual sector studies. In addition, there are brief general discussions of problems and possible future approaches to handling multisector models of agricultural production, transportation, and marketing (K. A. Fox), metal-working (T. Vietorisz), and economy-wide development planning (T. Vietorisz). The chapters by Vietorisz are particularly stimulating overviews. The brief appendix entitled "Basic Concepts of Activity Analysis" is obscure from the viewpoint of a novice, fragmentary and unedifying for one already acquainted with the mathematical techniques, but apparently is only intended as a few prefatory words to its bibliography.

While this book gathers together a number of studies carried out since the mid-fifties, it is not a compendium of all the engineering production functions lined up on the shelf to date, and unfortunately no attempt is made to supply a complete bibliographic compilation of references to such studies. Even for the sectors here analyzed, the processed data offered in chapter appendices are not complete. If one should decide to move into the field, he had better contact the authors directly. Indeed, the book seems to be mainly intended to inspire potential research workers to carry on with the job of enlarging the body of sectoral studies, and increasing detail in areas already broached. The book is not addressed to students; it is written from the point of view of a professional worker explaining to his successor on the project just what has been accomplished so far, and offering exceedingly valuable practical suggestions about how to make the next ten years easier than the pioneering decade. From one paper to the next the authors protest: "This paper represents no more than a modest attempt to demonstrate the feasibility of constructing a process analysis model for a single sector." "The new models which we have underway make several improvements over those summarized here." "The problem of analyzing the capabilities of the metal-working industries, it seems to us, is neither hopeless nor solved." "The reader would do well to remain skeptical about the specific conclusions reported here."

As would be expected, the multisector Mexican model is particularly unre-

liable. All sorts of unfortunate simplifications had to be indulged in to avoid searching out any more information than could be turned up within the summer of 1961: labor inputs were entirely neglected; the U.S. metal-working industries' technology described earlier in the book was transferred whole hog to Mexico; demands from several important extractive sectors (sulfur, coal, wood), as well as agriculture, textiles, construction and the distributive industries, remained exogenous in this model, in the same category as government and household final demand. The calculations were aimed at minimizing foreign loans and aid, subject to allowing the "key" sectors (electricity, rail freight, heavy chemicals, paper, oil, steel, aluminum, copper, cement, and certain metal products, including capital equipment for the key industries) to expand in order to satisfy the demands associated with two alternative growth rates of real GNP, 5.5 per cent and 8.0 per cent over the decade 1960-70, and at the same time to ensure compound growth in investment activity so that the GNP growth rate would continue beyond the planning horizon. The reader may remain skeptical of the results, as advised, but he would do still better to remember that short-order decisions in these important areas are continually being made, if only by default. A close look at the intricate workings of a technical mechanism will give more aid in controlling the apparatus than just winding it up and trusting its maker.

*Steel Decisions and the National Economy.* By HENRY W. BROUDE. Yale Studies in Economics No. 16. New Haven and London: Yale University Press, 1963. Pp. x, 332. \$7.50.

In this study, Professor Broude applies a variety of analytic methods from economics and related disciplines to the examination of some aspects of U.S. steel industry performance. Specifically, he asks: (1) To what extent have limitations on steel capacity constrained U.S. economic development? (2) How are management decisions concerning investment in steel capacity made in response to external demand conditions and internal corporate objectives? (3) What, if any, policies should be adopted to improve the response of the steel industry to national economic needs?

Broude first investigates the extent to which steel has played a critical role in cyclical and secular movements of the economy. He finds little historical evidence of stability in capital-output ratios for steel or of stability in relationships between steel and total output. Nor does he find that investment in steel capacity is potentially significant enough to forestall the upper turning point in a boom, except under the most rarified and critically timed conditions, although outlays in steel might play an important role in a larger investment program.

Broude then examines the extent to which bottlenecks in steel could constrain growth during an upswing. He presents a model with a constrained cycle characterized by accelerator and multiplier feedbacks, similar to those developed by Hicks and Goodwin, with the process dependent upon discrepancies between desired and actual stock. Although this model is not empirically im-

plemented, it does demonstrate the theoretical possibility of the constraining effect that selective underinvestment, e.g., in steel, can exert upon the economy. While recognizing that overcapacity has also been a problem in the industry, Broude concludes that steel shortages have in fact at times limited the growth of the economy. This conclusion would have been strengthened if it could have been shown rigorously in a general equilibrium framework that shortages of steel were more crucial than shortages of other outputs.

Broude examines reasons for these shortages, beginning with the quality of demand projections for steel. He finds that within the steel industry, demand projections, which have generally been based upon time-trend projections, output per capita, and other simple relationships, consistently exhibit a strong downward bias. Government and academic economists, whether using similarly primitive or more sophisticated techniques, have generally arrived at projections of capacity requirements that were much higher and closer to the steel consumption which actually developed.

In order to explain this divergence between national requirements and steel industry projections of capacity needs, Broude makes a study of entrepreneurial behavior, attitudes, decision-making, and planning practices in the steel industry. Using a combination of approaches, including interviews, role perception, organization theory, content analysis, and case studies, Broude develops a concept of the "representative entrepreneur," whose attitudes and motivation influence the steel industry view of capacity requirements. This "representative entrepreneur" is a servant of management capitalism, who is not so much concerned with profit maximization, technological innovation, competition, and risk-taking as he is with his own prestige, power, job security, corporate continuity, protection of sunk capital, social approval, and public relations. Broude cites these factors, in conjunction with fear of idle capacity, as forces which have contributed to downward bias in industry projections of requirements for steel capacity.

More accurate projections of steel capacity requirements have been made by government and academic economists, using two major approaches. The first is regression analysis, which typically has not related steel output to needs of specific purchasers, but does have the advantage of reflecting the effects of major underlying trends, such as technological change.

The other approach, which Broude finds much more promising, is structural analysis of the Leontief interindustry type, which treats consumption of steel as a function of the output of all major steel-consuming sectors, and which explicitly relates changes in the size and composition of final demand to changes in consumption of steel. In a dynamic formulation of the interindustry model, he is able to account for interactions between output, investment, and changes in direct and indirect requirements for steel. The conceptual model is not empirically implemented, and Broude does not examine the predictive success or reliability of interindustry models to date. Nor does he discuss the operational problems that would arise in actual application of interindustry models to the problems of projecting steel capacity requirements. However, Broude expresses confidence that advances in the work of Leontief, Orcutt, Klein, Koopmans, and others, will provide techniques for making reli-

able projections of the steel capacity required to meet national objectives.

Broude examines a wide range of public policies which might be designed to assure sufficient investment in steel capacity. He rejects the usual proposals for public regulation or intervention, which he fears would unduly disrupt existing institutional structures. His major recommendation is for the establishment of a federal review board, whose primary function would be to project steel industry capacity requirements in light of the public interest, within guidelines suggested by the Employment Act and by national economic growth objectives. Broude concludes with the hope that participation on such a public board would impart to steel industry leaders a more affirmative outlook concerning U.S. economic growth and a greater willingness to build forward capacity. He also notes that the creation and maintenance of excess steel capacity should be accepted as one of the real costs of economic growth, and he recommends appropriate tax relief.

In focusing sharply upon one public policy question in the steel industry, i.e., capacity shortages, Broude omits examination of significant related factors, such as wages, prices, profits, and international competition. It is scarcely conceivable that a fact-finding board would be able to analyze capacity problems in isolation from these other fundamental issues. Assertion of the public interest in determination of these policies for the steel industry might well lead to similar intervention in other critical sectors of the economy. Thus the logic of Broude's analysis draws attention to a widening range of policy questions related to national economic performance, now left to the initiative of corporate management, in which there may emerge valid grounds for public participation.

If this should prove to be the case, Broude's own eclectic blend of methodologies from economics, sociology, and related disciplines very ably points out many of the problems and potentialities inherent in such an approach.

*The Transport Problem.* By C. D. FOSTER. London: Blackie & Son, 1963. Pp. xii, 354. 40s.

The tendency in the United States has been toward specialization in the analysis and the discussion of transportation policy. The problem typically is divided into a series of subproblems, e.g., competition for intercity freight between railroads, trucks, barges, and pipelines; competition for intercity passenger travel between the private automobile, air lines, buses and railroads; and competition for urban commuter travel between public transit and private autos. Mr. Foster, by contrast, includes in his rich and diverse treatment of Great Britain's transportation problems and policies all British domestic transportation, excepting air.

This difference in the analytical approach and empirical content between Foster's book and its counterparts in the United States is partially justified by differences in the distribution and density of population, differences in the distribution of freight and passenger traffic as between modes, and differences in the adequacy or extent of redundancy of capacity of the various modes.

There is obviously a much greater interdependence between inter- and intra-city freight and passenger traffic in Great Britain. British railroads still provide for relatively large amounts of commuter and intercity passenger traffic.

This broader and more general view of the transportation problem is more justified, and possibly even essential, in the British context. For that matter it might even be desirable for the analysis of some U.S. problems where conditions approximate those in Britain. But it is not accomplished without some losses. In particular, the analysis and discussions of policy lack some of the sharpness and detail that might have been obtained from the analysis of a narrower range of problems. While this does not necessarily detract from the book's usefulness, it may cause it to appear somewhat shallow at points to the U.S. transportation specialist.

The book "is primarily about Government policy, discussing the issues raised by the decisions the Government has to make, particularly in two capacities—through the Ministry of Transport for roads, and through the Ministry and the British Railways Board for railways" (p. 1). The first of its four sections evaluates and discusses a number of simple, and, in Foster's view, unacceptable, solutions to rail and highway problems; presents some alternative policies that might be followed by public enterprise; and introduces Foster's basis for an economic solution of the transport problem. The second and third sections discuss rail and road problems in some detail; and the final section is primarily a tour de force in support of "consumer surplus maximization," Foster's chosen solution to "the transport problem."

Most professional economists will like many of the book's policy recommendations. However, they certainly also will be dissatisfied with the rather cavalier abandonment of marginal cost pricing in favor of "consumer surplus maximization." The majority of economists, who would instinctively turn to marginal cost pricing as a pricing policy for public enterprises, will be less distressed by the attempt to develop an alternative investment criterion and pricing policy than by the manner in which marginal cost pricing is dismissed. "The damning objection to using it [marginal cost pricing] as the guiding principle for solution of the transport problem is that there would seem to be no chance of its political acceptance. An economist building his recommendation on this foundation would not be listened to" (pp. 29-30). This, the sole reason offered for choosing his "consumer surplus maximization" over marginal cost pricing, seems totally unsatisfactory. What is, and is not, politically acceptable is extremely transitory and much subject to judgment. Moreover, comparative advantage would argue for leaving such decisions to others, and to the politician in particular. It is the economist's responsibility to spell out in some detail the implications of alternative criteria and alternative policies, leaving the politician to convert these judgments into public policy. The book suffers from the author's effort to combine the roles of theoretical economist and policy maker. The book has much excellent analysis and would certainly have been improved if it had been segregated from the campaigning for "consumer surplus maximization," which Foster clearly sees, to a greater extent than seems necessary, as the cornerstone of his policy recommendations.

There are, moreover, theoretical difficulties with his "consumer surplus maximization." It is not always possible to be certain precisely what "consumer surplus maximization" consists of, but it clearly implies average, as opposed to marginal cost, pricing. Furthermore, "consumer surplus maximization" would at first appear to imply a zero rate of return, or profit, on invested capital. Efforts to provide precision on this point produce, on the whole, more confusion than enlightenment. For example, "a consumers' surplus policy is also compatible with the retention of profits to form reserves" (p. 12). And, "a consumers' surplus policy is compatible with requiring an enterprise to pay the interest costs of the capital it uses" (p. 122). Summing these and various other profits which a "consumer surplus maximizing" enterprise might be permitted, or required, to earn, it appears that, in fact, the rate of return might have to be sizable, and conceivably might even exceed that for a private firm.

There are, moreover, additional theoretical difficulties. Foster states that the objective of the firm should be to maximize the consumer surplus of the consumers of the firm's product. In the case of railways, for example, he states, "we will define our consumers' surplus policy as one in the interest of consumers of railway services, that is, simply railway-users" (p. 117). However, it is not clear whether this includes only current consumers, given existing prices of railway services and of all other goods; all potential consumers at prices dictated by consumer surplus maximization; future consumers; or several other groups of actual or potential consumers.

In general, the book's treatment of the rail problem is vastly superior to its treatment of the road problem, although it is hard to explain the author's failure to bring to bear on his discussion of railway costs the very considerable amount of statistical costing carried out for railroads in the United States and Canada. The discussion of the roadway problem will seem fairly elementary to U.S. economists. Nearly all of Chapter 11, for example, is devoted to a fairly elementary description of a cost-benefit analysis of the London-Birmingham motorway. However much English readers benefit from this presentation, it will seem dated to the U.S. reader.

Despite these reservations, the book deserves the attention of all those concerned with transportation problems since it is a valuable contribution to the growing literature dealing with the economics of transportation. Although much of the policy discourse concerns English problems, and its greatest potential contribution is certainly to the growing debate about Great Britain's transportation policy, U.S. economists, and transportation planners and policy makers everywhere, will certainly benefit from reading the book. While readers may not entirely agree with the author's policy prescriptions, its worth by no means depends on either the correctness of the proposed solutions or their adoption.

*Modern Transportation Economics.* By HUGH S. NORTON. Columbus: Charles E. Merrill Books, Inc., 1963. Pp. 463. \$8.00.

Any author approaching the task of writing a usable college textbook in as

broad and diverse a field as transportation faces a number of difficult decisions. He must decide, for instance, how descriptive he intends to be, how much discussion of current policy issues and problems he will include, how much history and development of regulatory institutions and the field itself is desirable, and how much application of current managerial practices is needed for complete understanding. No doubt the compromise solutions to these problems contained in Professor Hugh Norton's text will not satisfy all persons in the field. However, by and large, Norton has produced a readable and teachable text which makes a definite contribution to the literature in the field even though it has several weaknesses.

Norton continues the laudable trend toward shorter books. He states at the outset that the text will not be an exhaustive reference book, and it is not. This book leaves the instructor a good bit of latitude to cover material in lectures and outside readings and to use other supplementary devices. Such an approach is desirable if the text itself provides a good foundation upon which the student may build. This is the case with this text.

Norton also continues the desirable trend of using an approach which integrates the various modes of transportation (rail, motor, air, water, pipelines) into the discussion rather than treating each separately. He does this job exceptionally well even though separate chapters are included on the regulation of railroads, regulation of motor carriers, regulation of air carriers, etc., as well as separate descriptive chapters on each mode.

The attempt to integrate economic theory (both micro and macro) into all parts of the discussion of transportation is somewhat less successful, although Norton does go a long way toward this stated goal. Use of theory considerations, graphs, and repeated references to theoretical works are scattered throughout. Yet, in total, one wonders if perhaps the task Norton sets himself is too great considering the limitations of length, or perhaps the integration of economics and transportation is an impossible goal.

Norton makes very good use of the technique of including a "summary" at the end of each chapter and has a number of lists of "Selective References for Further Study." Unfortunately, the listing of references for further reading is not carried out uniformly and at times is too limited.

The desire to keep things short shows up most noticeably in Norton's tendency to list in tabular form and his disarming propensity to write some chapters almost completely in a slightly expanded outline form. While the "skeleton" is there for the instructor to "flesh out," the student may at times skip over many important and pivotal points or fail to recognize or appreciate that all points in the list or outline should not be equally weighted.

Of the five parts of the book, Part I, "The Industry and the Modes: An Aggregate View," is by far the strongest and the best. Norton has provided an excellent overview or survey here and has good balance in a well-written and surprisingly brief description. The last part, Part V, "Problems and Prospects," is also very well written and is almost as strong as Part I. While the three chapters in this part are somewhat disconnected ("Carrier Management Problems," "Problems and Policies of Regulation," "Review and Policy Consideration"), Norton comes through here as an individual and scholar more

than any other place in the text. A number of provocative questions are raised, analyzed, and discussed meaningfully. The only weakness here is that the student may not have adequate background from the other parts of the book to fully use and appreciate Norton's excellent policy discussion or realize the full import of the points analyzed.

Part II, "The Economics of the Industry," and Part III, "The Basic Framework of Public Control," are the weakest sections of the text. Part II, too brief and segmented, covers transportation cost, demand, pricing, and rates too lightly and with too little analysis. Such important aspects of transportation deserve better treatment. Elasticity of demand is weakly considered, the classification system and various pricing systems (rate structures) are not well developed. Some applications, illustrations, and development of economic relationships would help these chapters. Perhaps the strongest chapter in Part II is the brief discussion of resource allocation. Part III is mixed. The discussion of the background of regulation tends to be too brief, and the use of the outline form may rob the student of a meaningful understanding of the institution of control. Here the instructor will certainly wish to lecture and supplement Norton. Finally, the chapter on administrative agencies and policy making shows Norton's excellent grasp of the subject, but unfortunately brings up solutions to policy problems not yet posed at this point in the text. Some instructors may wish to delay the students' reading of this chapter until the problems are better discussed in Part IV.

Part IV, "The Application of Public Controls," contains some excellent chapters (Chapter 17 on fair value and rate level, and Chapter 20 on control of competition are especially good) as well as some chapters which again illustrate the author's tendency to list, outline, and be overly brief. (Chapter 13, "Regulation of Railroads," Chapter 14, "Regulation of Motor Carriers," and Chapter 19, "Control Over Rates," illustrate this approach.) The remaining chapters, covering regulation of air carriers; regulation of water carriers, pipelines, and indirect carriers; discrimination; and consolidation and integration are very adequate and keep within the stated objectives of the text.

On balance, Norton's work is a contribution to the field that will be welcomed by many instructors, especially those well versed in this area and able to use supplemental materials. As a whole, the weaknesses are more than offset by the strengths, and a readable and teachable text is the result.

*Natural Resources and International Development.* Edited by MARION CLAWSON. Baltimore: Johns Hopkins Press for Resources for the Future, 1964. Pp. xi, 462. \$7.50.

Students of the problems of economic development must be grateful to Resources for the Future for these essays. They maintain a remarkably high standard for a volume of "commissioned" conference papers on a subject

which seems to call forth a disproportionate number of repetitious generalities about what is wrong, together with vacuous prescriptions about what ought to be done about it. At least four are of outstanding interest: M. A. Adelman on oil, for originality; Anthony Scott on fisheries, for concise and imaginative treatment; Arthur Gaitskell on Africa, for shrewd wisdom, compassionate understanding, and English style; and Chandler Morse on private foreign investment, for a balanced and comprehensive discussion of a difficult subject.

The ten papers are grouped under three headings. The first, "Commodities of International Significance," contains papers on agriculture, oil, and fisheries. Perhaps the most disappointing of the papers is that by D. Gale Johnson on "The Role of Agriculture in Economic Development." His primary conclusion is that increasing productivity in agriculture is essential for economic development—a conclusion that hardly startles us. Johnson does not deal with agriculture in general, but only with food production, and he shows that the demand for food has grown at different rates in the industrial and nonindustrial countries and in different areas of the world, that the poor countries are faced with a rapid rate of growth in demand, and that the policies of the rich countries are detrimental to the development of the poor countries. Most of the discussion is general, relying heavily on "aggregate" data covering large areas of the world without reference to the doubtful quality of agricultural statistics in undeveloped countries or to the great differences between countries in the same region, and is written in a style clumsy, at times unclear, and in places even ungrammatical.

Adelman's paper on "The World Oil Outlook," by contrast, is a remarkable tour de force, challenging and effectively demolishing the almost universally held view that oil production is inherently subject to long-run "decreasing cost," and presenting in a workmanlike, lively, and witty style, the best analysis I have ever seen of the basic economics of the industry. He shows that, subject to random disturbances (an important condition), output can be expected to adjust to price changes through the usual mechanism of rising marginal cost acting against marginal revenue, although he recognizes that the adjustment may at times be difficult and painful and may thus be socially and politically unacceptable, especially in the presence of much excess capacity. This is a first-class piece of work which is not only an important contribution to the study of the international petroleum industry, but also an outstanding model of how economic theory should be applied.

Anthony Scott in "Food and the World Fisheries Situation" discusses the reserves and productivity of the oceans, the economics of fisheries, and various forms of international cooperation in their exploitation. I find it extraordinary how little we seem to know about wild fish, and Scott explores, briefly but imaginatively, the possibilities of man increasing this source of food through knowledge and appropriate management. The paper is but a prelude to a longer forthcoming study, which should be of great interest.

The next general section of the book deals with "Resources in Europe, Africa, and Latin America" and contains essays on the Soviet Union (Dimitri B. Shimkin), Europe (P. Lamartine Yates), Africa (Arthur Gaitskell), and Latin America (Joseph Grunwald). Shimkin gives a valuable and extensive

statistical survey of resources and their use in the Soviet Union and adds some remarks about Soviet allocation procedures. Grunwald analyzes some of the special problems created for developing countries by foreign exploitation of their raw materials and describes, again statistically, some aspects of the importance of natural resources for the development of the Latin American countries. Yates discusses the manpower, agriculture, forest lands, and energy of Western Europe and shows how very rich the continent is in these resources, although it will have to depend increasingly on imports of energy to meet its growing demand. The efforts of the Common Market countries to obtain self-sufficiency in agriculture are described, but the significance of European agricultural autarky for third countries, and especially for the underdeveloped countries, is not analyzed. Yates merely asserts that the improved economic strength of a "united and rich Europe" will in the end benefit the rest of the world. He seems to be little disturbed by strictures contained in some of the other essays about the adverse effect of protectionism in the rich countries on both the rich and the poor countries.

The most outstanding essay in this section is that of Arthur Gaitskell, "Resource Development Among African Countries," which, I again suggest, should be required reading for students of economic development. Mr. Gaitskell does not attempt to catalogue the resources of Africa but, instead, describes the nature of the environment and the changing position of man in the area as the result of political changes and the rise of the independent African states, primarily in "British" Africa. His discussion of African attitudes towards development and the ways in which the Western world can fit in with these attitudes, if it so desires, is marked by a shrewd understanding of both worlds.

The third section of the book, lamentably labeled "Problems, Situations, Processes," contains three papers. Charles Kindleberger gives us a lively, brisk, and down-to-earth essay on the "Terms of Trade for Primary Products." After an admirably succinct review of the various arguments about and statistical analyses of the subject, he turns to discuss the future in the light of the different policies recommended or adopted by various governments and organizations. Kindleberger frankly recognizes the conflict that has appeared between an acceptable distribution of income and an appropriate allocation of resources: "The fact is that the world does not know how to stabilize commodity prices in ways which will produce the appropriate distribution of income without messing up the allocation of resources in production" (p. 361). Discussing somewhat flippantly (and indeed cynically) the various propositions designed to evade the dilemma, he ends with his own prescription: "not much primary-product price stabilization, . . . and all of that temporary, and accompanied by foreign aid for the purpose of alleviating dependence on limited specialization" (p. 362).

In the second paper, on "Potentials and Hazards of Direct International Investment in Raw Materials," Chandler Morse has produced a masterly and well-balanced discussion of this intricate issue, one of the chief merits of which is its open recognition of the extent to which private investment is not an unmixed blessing for the undeveloped countries. His careful discus-

sion of differences in legal systems and social attitudes between the Western world and the undeveloped countries goes to the root of many problems and is a refreshing change from the carping and superficial criticism which characterizes the attitudes of many Western businessmen and economists. His review of the literature, mostly in footnotes, is remarkably complete, and the essay as a whole will provide a valuable and balanced introduction for students. Only occasionally is his clear and straightforward style marred by the use of jargon which can be justified neither by the technical nature of the discussion nor by the demands of precision. It is not excusable in an essay of this type to describe the role of society's political institutions as the control of "The parameters of private choice functions," or to talk about "efficiency paths defined by the parameters of a situation" (cf. p. 409).

The concluding brief essay by Egbert de Vries on "International Transfers of Knowledge and Capital" is somewhat scrappy but it stresses one important point often overlooked—the danger of losing information either because reports disappear in private or governmental files or because so much is drowned in the vast seas of material. He urges the importance of establishing international procedures for retrieving information.

The book is well indexed; some of the essays have extensive statistical appendixes, and many contain much useful bibliographical material.

*Location and Land Use—Toward a General Theory of Land Rent.* By WILLIAM ALONSO. Cambridge: Harvard University Press, 1964. Pp. xiv, 204. \$5.50.

The bulk of this ingenious book is devoted to the construction of a model of the equilibrium pattern of land use and land values in a city. This city is in a featureless plain, and proximity to its center is assumed to be attractive to all land-users. The central tool of analysis is the bid price curve, a line joining those combinations of land price and distance from the city center between which the land-user is indifferent.

Families of bid price curves are rigorously derived by price-theory type of analysis for each of three types of land use: agriculture, urban firms, and residential. In the last case, for instance, the individual's utility is assumed to be an increasing function of the size of his residential lot and of his consumption of other things, and a decreasing function of commuting distance. He maximizes utility subject to a budget constraint upon the sum of his expenditures upon his lot, upon other things, and upon commuting (whose cost is an increasing function of distance from the city center). Given his income, his commuting-cost function, and the price of other things, he will have one single-valued bid price for each level of utility. In the same way, farmers will have a bid price curve for each agricultural product price level, and an urban firm will have a bid price curve for each level of profits. These curves all show bid price falling as distance from the center increases; and they take into account the optimization of the size of lot for each price and location.

The next step is to analyze the equilibrium constellation of lot sizes, loca-

tions, and land prices, given the number of residents, the agricultural price level, and the number of urban firms. This is done in Chapter 5, where it is shown that, given well-behaved bid price curves, "in general, the steeper is his bid price curve, the nearer the center of the city will a user of land locate." Another way of putting this would be to say that central locations are occupied by those who put the highest premium on proximity to the center.

The analysis summarized so briefly here takes up a good deal of space. To say this is not to complain, however, for Dr. William Alonso has set it out both algebraically and geometrically and has provided intuitive explanations of his results. That the harvest is relatively meager for such a large effort is disappointing but not surprising, since formal rigor in economic theory often requires a great deal of elaborate technique.

Alonso regards his theory as relating to the long run, i.e., as concerning the equilibrium pattern of land use. Thus the occupant of one floor of an  $n$ -story building can be regarded as occupying a site whose size is one  $n$ th of that of the building. A complete analysis would therefore have to include consideration of the costs of building high and of preferences between ground-floor and upper-floor location. Since these factors are left out of the analysis, Alonso's theory could equally well be regarded as relating to the short run, explaining the equilibrium allocation of a given amount of floor space in a stock of existing buildings.

For those who do not enjoy technique for its own sake, the main interest of the book will be in its final chapter: "Some Applications of the Model and an Outline of Empirical Research." It starts with a convincing refutation of the Haig notion that the equilibrium pattern of land uses and land values minimizes costs of friction. It is interesting to note that the argument here hardly rests upon the model developed in the first part of the book, and that when the model is used in subsequent sections, its consistency with observed phenomena (e.g., peripheral location of higher-income residents) is not necessary: it would also be consistent with an alternative set of observations. The model, that is to say, is not a strong one, and it requires numerical values of some of the parameters to make it so. For this reason particular interest attaches to an empirical section where a regression with Philadelphia data shows that family expenditure on land is an increasing function of income and a decreasing function of distance from the center. On a theoretical plane there are also admirable sections on the effects of density zoning (though without any reference to external diseconomies) and on city shapes.

This brief mention of the topics discussed in the final chapter should suffice to show how stimulating it is. All that remains to be said is that, in a branch of economics too often characterized by purely discursive treatment, Alonso's book stands out for its rigor and clarity.

*Land Use Policy and Problems in the United States.* Edited by HOWARD W. OTTOSON. Lincoln: University of Nebraska Press, 1963. Pp. x, 470. \$6.00.

What significance for today's analysts can be found in the Homestead Act?

One answer is that the Act provides experience in adapting policies to problems arising from economic change. Concern with the adaptation of land policies to change is the main connection between the first third of this book, which looks back, and the last two-thirds, which is more current. Presented at a conference on the occasion of the hundredth anniversary of the Homestead Act, the contributions are primarily from economists experienced in analyses of land resources and institutions. Historians, political scientists, and a geographer are also represented.

The policies that finally culminated in the Homestead Act are viewed by some of the authors as retarding economic development and as political schemes enabling private citizens to obtain capital gains that might better have gone to government. Others defend the Homestead Act. As formalizer of the squatting method for public domain to pass into private ownership, the Act is seen to have speeded economic development by lowering the cost of settling and by making land use a condition of initial ownership. According to their views, the Act reduced the holding of idle large tracts for speculation and helped to distribute any private speculative gains to the less wealthy. Commendably, evidence is offered that throws light on whether the policies had these and other effects. Especially since some effects were favorable to economic development and some unfavorable, one hopes that future analysts will estimate the magnitude instead of only the sign of the effects. The essays mention numerous effects that deserve such estimation.

Thomas Jefferson is an absent and sometimes controversial contributor in the sense of receiving much mention. In a chapter on the present relevance of the Jeffersonian ideal, John M. Brewster concludes that the Jefferson ideal, interpreted as a family-farm goal, is still desirable and will be tenable until more knowledge about photosynthesis and animal feeding results in large-factory farming. W. B. Back believes that the family farm is only a powerful myth and that it cannot be defined usefully in a modern setting. One senses a differing political philosophy in the background of this disagreement that is more apparent than real. Both authors suggest that any fostering of family-farm goals will be successful and desirable only if consistent with income goals.

On another recurring theme, Brewster and Back and many of the other contributors agree: Modifications in ways of acquiring control over assets will be needed as the amount of resources used by a single farm continues to increase. Many years ago the old ideal of debt-free owner managership became obsolete, as profitable farm sizes grew so large as to be achievable only by borrowing or renting. With further growth in value of assets needed by a farm manager, there is now talk of modifying the old ideal more sharply by separating managership from farm firm equity through corporate forms.

Researchers might usefully carry further by estimating more specifically the future seriousness of this balance-sheet problem. One can point out that in many places in the South large land holdings have been kept intact between generations. A run of a few good years of income can enhance family wealth, with the result that a potential manager may inherit sufficient equity

to start a good farm even if he is from a large farm family. Relevant to recent years, sufficient inheritance can be made possible by accrual to families of capital gains on land. There might, too, be more concern about the incongruity of almost unconsciously assuming it is desirable to ease entry into farming when there are still surplus problems. Finally, a balance-sheet consideration that could be at least as important as the one so heavily emphasized is the vulnerability of present farm owners to adverse runs in income, such as could be brought on by weather or low prices, or asset-value losses that might accompany an adjustment in the rate of capitalization in the economy as a whole.

One section of the book that may be particularly valuable to nonland economists competently summarizes knowledge about demands on land by major categories of use: Harry A. Steele and Norman E. Landgren on agriculture, Raleigh Barlowe on recreation, and Lowdon Wingo on urban land.

Several other themes recur in sections widely separated from one another. Marion Clawson's general consideration of policy contemplates the changing interaction between interest groups, the public at large and professional land managers, and sees an increasingly influential role for the last. Ross Talbot's is almost a companion piece, providing a primer on politics of land and on the many government policies concerned with land. The Clawson and Talbot pieces, much more strongly together than separately, convey a picture of small rather than great changes underway in the over-all land-policy setting at the present time.

M. M. Kelso, Marshall Harris, and Gene Wunderlich, bringing in interdisciplinary considerations, explore, each in a different manner, criteria for land policy. Policy issues for Asia, Europe, and Latin America are analyzed by Walter Neale, Philip Raup, and Raymond Penn and Kris Kristjanson. They complete a circle providing an implicit reminder that present policy needs of other countries are as different from those of the United States as present needs are in this country from needs at the time of the Homestead Act.

To review this book is almost to review current land economics because it reflects well a large part of activity in the field. Strong points include rising theoretical competence, concern with looking ahead, attention to the right variables for analyzing policy, and operational contributions to administration and legislation. Some of these very features are suggestive of current needs to use more intensively the acquired economic theory in empirical analyses and, given recognition of the variables required for an adequate policy framework, to develop further the analytical context within which to use the variables. Four possibilities for making progress along these lines may be mentioned. First, there could be more estimates of magnitude of effects of alternative policies. Many needs exist in addition to those mentioned earlier for estimating output effects and regional, sectoral, and personal income distribution effects of present and contemplated programs. Second, drawing on the lesson of the impact that benefit-cost analysis has had, can we develop measures of the contribution of land-reform policies to economic development? In view of the recent attention to land reform, efforts now to devise

such measures might be more fruitful than they would have been several years ago. Third, while relevant goals have been recognized, there is still need to develop policy criteria. The criteria would aid in trading off between different goals, taking account of policy-making processes. Fourth, it would be desirable to encompass predictions of policy as well as predictions of economic events. Several of the contributions to this volume contain insights about probable future policies, indicating the feasibility of pursuing such analyses formally. These possibilities are mentioned to suggest, not that a different book should have been written, but that this book brings to mind a desirable sequel building on the progress it exemplifies.

*Dynamics of Adjustment in the Broiler Industry.* By B. F. TOBIN AND H. B. ARTHUR. Boston: Division of Research, Graduate School of Business, Harvard University, 1964. Pp. xii, 164. Paper, \$3.00.

This study deals with the growth of the modern broiler industry, a leading example of an "agri-business." Despite the growth of industrial volume, coupled with continued horizontal and vertical integration, the industry has been plagued by price instability and declining profit margins.

In the description of the technical production process, the authors demonstrate that they are able to observe the industry clearly and coldly without taking sides.

In the second chapter, the authors make a key point which is only partially understood by the industry—"markets are integrators just as truly as are contracts or mergers" (p. 41). In the third chapter, the authors try to show that the relationship of supply to demand is complicated by the several decision centers affecting production. These decision centers are not always correctly attuned to the final consumer demand on which, in their opinion, production should be based. In other words, a temporary supply shortage brings an overreaction by decision centers. Thus firms controlling the basic breeding stock may put too many units into production with resultant severe supply pressures 18 months later. The authors point out that the lack of effective coordination in the industry is a basically unsettling factor and that the "very forces leading to vertical integration were also unstabilizing." Basic production facilities were duplicated, leading to possible overcapacity.

In Chapter 4, the authors develop their major thesis that the decision centers controlling production must move toward the final point of sale. The developing industry has had to recognize the final market rather than falling production cost. One of the study's most interesting criticisms deals with how cuts in bulk grain freight rates have stimulated southeastern production without regard to the total consumer demand for finished broiler meat.

As a possible solution to the continuing price instability plaguing the broiler industry, the authors suggest three possibilities.

1. Consumer acceptance of frozen broilers with resulting ability to stockpile in periods of temporary glut. (However, the source of the additional working capital to finance the inventories is not mentioned.)

2. The use of demand marketing which would better schedule current production in terms of future markets.

3. Government control of supplies and industry acceptance of the fact that competition will not create equilibrium.

The authors believe that continued mergers and consolidations will eventually prove to be the final solution. This will be a "rational and not an exploitative process." It is interesting to note that the authors emphasize the economies of scale and better management as the end result of industrial "rationalization." They do not emphasize the factor that shifting from a purely competitive model to a monopolistic model may offset to some degree the oligopsonistic power of the relatively few large retail chains.

While human decisions are the key to possible solutions they are also the possible basis for continued instability. As the study shows, only a minority of the industry has to act irrationally to upset the demand-supply relationship.

In the final analysis, the industry resembles Schumpeter's concept of the role of innovation. Only a few businessmen have the imaginative power and energy to initiate successful new ways of doing old things. But while only a few can lead, many can follow. The crowd of imitators prevents the industry from settling down to a more profitable equilibrium point. Many theoretical questions are left untouched, but as a basic industry study, this work is admirable and highly recommended.

### Labor Economics

*Manpower in Economic Growth: The American Record Since 1800.* By

STANLEY LEBERGOTT. New York: McGraw-Hill, 1964. Pp. xii, 561. \$8.95.

This is *not* an economic handbook, despite inclusion in Seymour Harris' distinguished "Economics Handbook" series. Only a sadist would inflict it on students as a text. Neither is it a labor history, in the conventional sense of John R. Commons, his Wisconsin disciples, or their Socialist opponents. Neither "trade unionism" nor "labor movement" appears in its 10-page index; the single reference to "strikes" refers to 1835-36; "Lewis" is the Chicago economist H. Gregg, not the U.M.W. hero John L.; and so on.

Well then, what manner of witches' brew has Professor Lebergott served up for us? Primarily, he has done for U.S. labor force, employment, unemployment, and wage statistics for the period 1800-1960 the kind of job which Simon Kuznets and Raymond Goldsmith have done for U.S. national income, wealth, and capital statistics over a period roughly half as long. Nor is it only in the size of historical canvas that Lebergott at times out-Kuznetses Kuznets and out-Goldsmiths Goldsmith, but in two other features of his work as well. One is the tender loving care of his literary style. It really matters, for example, not only to Lebergott but to his readers, that faulty census-enumerator instructions led in 1910 to overestimates of the labor force and employment as compared to censuses prior and subsequent; and it matters, too,

what adjustments had best be made to "the facts" as reported, to make the 1910 data comparable with the rest. An allied feature of Lebergott's presentation is humbleness. Any reader, even the most casual, can see the chewing-gum and baling-wire with which the estimates were put together (unless of course he limits himself to copying figures) and the enormous variations between different estimates of the same entity for the same period, particularly if that entity is unemployment.

This reviewer must confess to being more impressed with Lebergott's one-man National Bureau set of tables, broken down by age, sex, race, region, and/or occupation, and with his labor of choice among alternative estimates (plus defenses of the choices made) than with the resultant economic history which forms Part I, "Sources and Consequences of Growth." Two major factors, copiously documented but largely independent of the detailed statistics which follow, are, (1) the pressure for labor-saving invention and innovation, brought on less by the height of U.S. wages than by the expectation of their long-term increase, and (2) a steady decline of the "uncertainty" factor in both labor and capital costs, as markets, law, and order were extended across the continent. It is largely by these that Lebergott explains the simultaneous growth in the labor force and in income per worker, to the relative neglect of enlarged educational and training opportunities, which Edward Denison regards as paramount in his study of *The Sources of Economic Growth in the United States* (Washington: Committee for Economic Development, 1962). It is regrettable that Lebergott provides no direct confrontation of his surmises with Denison's. This reviewer's guess, which may reflect primarily the occupational bias of the professional educator, is that Denison is more nearly right than Lebergott, but crucial experiments distinguishing between the rival theories have yet to be undertaken. (Dissertation hopefuls please note.)

*Labor Markets, Unions and Government Policies.* By EVERETT JOHNSON BURTT, JR. New York: St. Martin's Press, 1963. Pp. xix, 454. \$8.75.

There are two traditions of textbook writing in the labor field. One tradition is embodied in those texts which seemingly encompass anything that could be taught under the rubric of labor. Their contents range from labor market analysis to trade union history and institutional practice; labor market and social welfare policy to industrial relations processes and procedures. The other emphasizes the economics of the labor market and analysis of the relationship of manpower problems, policies, and institutions to basic socio-economic phenomena.

Happily, this work is in the latter stream of thought. It attempts, though not always successfully, to utilize economic analysis as a tool for understanding labor and job markets in a world of trade unionism, collective bargaining, and governmental welfare and employment policy. Further, it reflects the substantial changes in emphasis which have been occurring in labor economics as a result of recent attention to key manpower problems and to the economics of the utilization of the human resource.

Everett Burt avoids that encyclopedic descriptive type of emphasis that induces many economists and analytically oriented undergraduates to feel that the field is either devoid of genuine analytical content or is unrelated to the central core of economic theory. Instead, stress is placed upon the essentials of our discipline, including labor market theory and the analytical basis for present day labor market, social welfare, and manpower policies. This textbook should assist the student in understanding how the economist defines labor problems and how he uses his tools to try to solve them. From the student's or worm's-eye point of view, it is eminently satisfactory because it is readable and interest evoking.

The book can be divided into five sections: (1) The Labor Market, Its Dynamics and Structure, (2) The History, Structure and Nature of American Trade Unions, (3) Collective Bargaining, Objectives and Policies, (4) Wage Theory, Wage Structure and Union Impact upon Wages, and (5) Economic Security and Governmental Policies. If one agrees with the author's premise that the union movement is an outgrowth of the problems facing the worker as a supplier of labor, one should not then quarrel with his sequential development, e.g., introducing labor market analysis before union history, collective bargaining, wage theory, and current governmental labor policy. But it would be missing the obvious to deny some compensating disadvantages and awkwardness stemming from this approach. For instance, since the chapters on labor markets and union wage objectives in collective bargaining are presented before the chapters on wage theories and wage structure, the student may find it difficult to perceive either the effect of union wage policy upon allocation of the labor supply or the validity of the stated separation between the wage and job markets.

The most meritorious features of this work result from the author's ability to differentiate between the important and less important and to omit the latter. Much of the recent research in labor economics has been blended into the analysis. Additionally, the work covers some basic but often neglected topics such as equalizing differentials, union and governmental effects upon wage rates, and the theory of the labor movement. Burt is not merely content to describe such subjects as the internal wage structure, work rules, and wage differentials. Instead, he consistently attempts to apply the analytical tools previously developed in the work to understanding these phenomena. Full employment, economic security, and labor market policies of the federal government are generally well described and analyzed. Considerable ability to utilize effectively recent research is displayed in the analysis of minimum-wage legislation. The discussion of work versus leisure and the short-run labor-supply curve shows insight into both the theoretical and applied literature and is one of the more satisfactory features of this work. Another excellent discussion is on contract regulations and the economic basis for bargaining power. In general the author has successfully avoided the pitfalls of many labor and industrial relations texts, namely of confusing description with analysis.

Other sections, however, are less well executed, and even the implementation of many of the unique features of this text leaves much to be desired.

This reviewer must report much more satisfaction with coverage, emphasis, and design, than with execution.

Burt's discussion of equalizing differences is confusing and fails to cover the major causes for their existence. His analysis of theories of the labor movement is oversimplified and does not provide any rationale for understanding either the theories or how they can be related to the specific growth process of American trade unionism. The author fails to relate union attitudes and work rules, many of which superficially seem nonrational, to the economic problems arising during organized labor's history and growth. The discussion of corruption and racketeering fails to focus upon relevant questions: what, for example, are the work environments and labor market situations in which invidious practices are likely to appear? The chapter on "Theories of Wages" is, at best, too episodic and, at worst, fails to develop insights into the nature of the fundamental forces impinging upon both the aggregative wage level and wages in different occupations.

Despite these and other defects that stem from failure to make some necessary qualifications and the use of value-laden terminology, the text meets the test as a satisfactory teaching instrument. It asks most of the right questions, and its emphasis upon how the labor economist answers them rather than upon the answers themselves is a proper one. In his avoidance of that defect characteristic of the more encyclopedic texts of "being all things to all men," Burt manifests some substantial ability to vitalize the subject matter and stimulate the student.

#### UNESCO

UNESCO wishes to ascertain the opinions of American economists regarding economic programs it had best undertake in the future. Accordingly, UNESCO and the A.E.A. have scheduled a joint session at the Association meetings in Chicago, December 28-30. Meanwhile members of the Association are invited to submit written proposals for consideration by UNESCO; some of these will be discussed at the joint session, together with the role of UNESCO in the field of international economic inquiry. A panel discussion may be utilized. Members who have suggestions or proposals may send them to Kenneth Boulding, Economics Department, University of Michigan, Ann Arbor, Mich., or to Joseph J. Spengler, P.O. Box 4723, Duke University, Durham, N.C. Those desiring basic information on UNESCO may address: Program Officer for the Social Sciences, U.S. National Commission for UNESCO, Department of State, Washington 25, D.C.

#### ART EXHIBITION

Arrangements have been made for an art exhibition in conjunction with this year's Annual Meeting of the A.E.A. Members who would like to display one or more of their works at the exhibition should write by October 31 to Harry G. Johnson, 1126 E. 59th Street, Chicago 37, indicating the number of works, the medium, and the space required for display. (It may be necessary to ration display space, as accommodation in the main convention area of the hotel is limited.)

#### NEW JOURNALS

Under the title *Co-existence*, a new journal began publication this year. The journal is devoted to "the comparative study of economics, sociology and politics in a changing world." It "will advance responsible thinking on co-existence, which is recognized as the alternative to the cold war. . . . The Journal will include survey articles, correspondence and documentation."

The editor is Dr. Rudolph Schlesinger, Inverloch, Kilmun by Duncon, Argyll, Scotland.

A new journal, *Demography*, began publication this year. It is a publication of the Population Association of America; the editor is Donald J. Bogue, 1126 E. 59th Street, University of Chicago, Chicago, Illinois 60637.

### DIRECTORY OF WORKERS IN THE ECONOMICS OF FORESTRY

The Division of Forest Economics and Policy of the Society of American Foresters is in process of compiling a world-wide directory of workers in the economics of forestry. The Division plans to include the names of all persons who have a major professional interest in economics as applied to producing, harvesting, processing, marketing, or consumption of forest products or services.

Registration forms for the directory were mailed during the first week in September to all forest and forest-industry economists of record. Those who do not receive forms but who wish to be included in the directory are asked to write to the chairman of the directory committee: William A. Duerr, State University College of Forestry, Syracuse, New York, 13210.

### CORRESPONDENCE COURSE

The School of Extension Studies of the Industrial College of the Armed Forces invites managers in business, industry, and the professions to join senior military officers and government officials in studying the economic and industrial aspects of our nation's position in today's world through the correspondence course entitled "The Economics of National Security."

Admission requirements for private citizens are a bachelor's degree or 12 years of business experience; for military officers, the rank of major or above. Apply directly to the Commandant, Industrial College of the Armed Forces, Washington 25, D.C., Attn.: Correspondence Course Division.

### FELLOWSHIPS

The Office of the Comptroller of the Currency announces the establishment of research fellowships in banking and monetary affairs. Fellowships will be awarded to outstanding economists from colleges and universities for a period of up to one year, and holders will pursue their research in the Department of Banking and Economic Research in the Office of the Comptroller of the Currency.

The Society for Religion in Higher Education is offering a number of postdoctoral fellowships to encourage the growing interest in the relation of scholarship in religion to scholarship in other fields of study. These fellowships are made possible through a grant from the Danforth Foundation.

Grants are available to scholars in the humanities, social and natural sciences for a year of study in religion and to scholars in religion for a year of study in another discipline. These fellowships are open to scholars in any institution of higher learning in the United States or Canada without respect to discipline, religious affiliation or non-affiliation. Scholars applying for these fellowships grants must have a Ph.D. degree or its equivalent plus at least three years of teaching experience. Preference will be given to scholars under 50 years of age. The maximum stipend is \$8,500. Stipends will be based on experience, present salary, and availability of other resources.

Completed applications must be received by the Society by December 1, 1964. Application forms and additional information may be secured from Lawrence P. DeBoer, Executive Director, The Society for Religion in Higher Education, 400 Prospect Street, New Haven, Connecticut 06511.

## RESEARCH EXPENDITURES, EDUCATION, AND THE AGGREGATE AGRICULTURAL PRODUCTION FUNCTION

By ZVI GRILICHES\*

Two previous papers [5] [6] summarized the results of estimating an aggregate agricultural production function based on 1949 data for 68 regions of the United States. The main findings of that study were the importance and significance of education as a factor affecting output and an indication of the existence of substantial economies of scale in agriculture. The present paper extends this study to cover the years 1949, 1954, and 1959, using per-farm state averages as its units of observation, and introduces explicitly the level of public expenditures on agricultural research and extension (the dissemination of research results) as a variable in the aggregate production function. The results of the current study indicate that these expenditures affect the level of agricultural output "significantly" and that their social rate of return is quite high.

### *I. The Approach and the Data*

The basic approach of this paper consists of estimating an unrestricted production function of the Cobb-Douglas type, using separate variables for each of the five major input categories, and introducing, in addition, a measure of education per worker and a measure of public expenditures on research and extension (*R & E*) per farm into the estimating equation. The data used are derived mainly from various U.S. Department of Agriculture publications; they are expressed as per-farm averages for 39 "states,"<sup>1</sup> and deflated by various

\* The author is professor of economics at the University of Chicago. This paper was written during his tenure as a Ford Foundation Faculty Research Fellow at the Econometric Institute, Rotterdam. It is part of a larger study of the econometrics of technical change supported by the National Science Foundation.

<sup>1</sup> Because of lack of data (mainly for the labor variable), some of the smaller states were aggregated into larger units. Thus all of New England was treated as one observation, and so also were Delaware and Maryland, New Mexico and Arizona, and Wyoming-Utah-Nevada.

national price indexes with 1949 (=100) as a base.<sup>2</sup>

This study differs from the previous one in that it investigates three cross sections of data simultaneously. This allows it to ask questions which could not be answered by the previous cross-section study. On the other hand, the 1949 study was based on data for 68 "productivity regions," while this study has to restrict itself to observing only 39 "states" at any one point of time. The lower number and the conglomerate nature of these states reduce sharply the observed range of variation in some of the "independent" variables and, hence, also the sharpness with which their individual influence on output can be estimated.

This study differs also from the previous one in the definition and measurement of some of the variables. It treats fertilizer as a separate variable (measuring it by weighted plant nutrients rather than expenditures), while combining other current expenditures with expenditures on purchased livestock and feed. It uses also a measure of land in constant prices which is free from contemporaneous influences of trends in product prices or urbanization and a measure of machinery services based on the aggregation of inventory data on individual machines, using prices of "new" machines as weights. The latter procedure results in a machinery-services measure based on "gross stock" concepts.<sup>3</sup>

## II. *A Digression on the Elasticity of Substitution*

Before we examine the main results of this study, it is worth while to investigate whether there is strong a priori evidence against the assumption of a unitary elasticity of substitution between labor and all other inputs implicit in the Cobb-Douglas form of the production function. This question can be investigated by fitting a log-linear relationship between output (or value-added) per man and the wage rate. Given the assumption of a constant elasticity of substitution (CES) production function [1], competitive product and factor markets and equilibrium, correct measurement of all the variables, and an exogenous wage rate, the slope coefficient in this equation is an estimate of the elasticity of substitution between labor and all other capital inputs (if value-added is used as the output variable).

The results of fitting such a relationship to various combinations of years and different forms of the equation and data are summarized in Table 1. The direct estimate of this equation (lines 1a, 2a, 3a) results in coefficients that are somewhat above unity. The other lines in Ta-

The basic equation estimated is of the form  $\log (VA/L) = a + b \log W + Zc + u$ , where  $VA$  is "real" value-added equaling sales plus inventory change plus home consumption plus government payments minus all current purchases of goods and services (except labor) from both outside and inside the sector, all individually deflated (1949=100) before subtraction.

$L$  is a man-days-worked measure of labor.

$W$  is the "real" wage rate per hour: composite hourly wage rate for hired farm labor, deflated in each state separately by the implicit output deflator.

$Zc$  is a shorthand notation for a matrix of other variables and the associated coefficient vector;  $u$  is a disturbance, usually assumed to be random and uncorrelated with the "independent" variables.

"Education" is a measure of formal schooling per male in the rural farm population, constructed by weighting the distribution of males by school years completed within each state by all U.S. mean incomes in each of these categories. See the data appendix and [6] for more details on the derivation of this and other variables.

"Time dummies" are shift variables that take the value of one for all states in their "reference" year and zero in all the others. Their introduction allows each cross section to have a mean level (intercept) of its own, while preserving the equality of slope coefficients. They allow for common time trends (and measurement errors) in the mean level of all the variables. Under the assumption of the CES model and neutral technical change, the coefficients of the dummies are an estimate of  $(1-\sigma)\lambda_t$ , where  $\sigma$  is the elasticity of substitution and  $\lambda_t$  is the rate of technical advance relative to the base period (in this case 1949). If one assumes that  $\lambda > 0$ , the slightly positive coefficients imply a  $\sigma$  of somewhat less than unity.

Lagged value-added per man is the lagged value of the dependent variable from the preceding cross section. That is, the lag is five years.

I.V. are estimates based on the method of instrumental variables, using the lagged ( $t-5$ ) wage rate instead of the current one as an instrumental variable.

The number of observations equals 117 for set 1, 78 each for sets 2, 3, and 4, and 39 for set 5. The numbers in parentheses are the estimated standard errors of the respective coefficients.

ble 1 reflect various attempts to deal with possible sources of bias in this estimate. An attempt to take into account differences in the quality of labor in different areas (the neglect of which would bias the estimated coefficient towards unity) by introducing a measure of education per man into the equation does reduce the estimated elasticity of substitution, but not consistently or significantly below unity. The possibility that the farm labor market is not in instantaneous equilibrium is investigated by fitting a distributed lag model of the Koyck-Nerlove type (line 3b). The resulting "long run" estimate of the elasticity of substitution is again above unity (but not significantly so). The possibility that the relationship may be due to the effect of omitting some regionally stable variables is investigated by fitting the same equation in the form of first differences, relating *changes* between cross sections in output per man to changes in the wage rate (line 4). Finally, the possibility that the results may be due to simultaneous-equations bias, since the farm wage rate may in its turn be affected by the same forces that determine the level of output per man, is investigated by fitting the same equation, using the method of instrumental variables (and the lagged real wage rate as the instrumental variable) instead of the method of least squares (lines 5a and 5b). Neither of these alternative forms of the model results in estimates of the elasticity of substitution which are significantly different from unity. Thus, at this level of aggregation, there does not seem to be any strong *prima facie* evidence against the Cobb-Douglas form, which will therefore be used in the subsequent discussion.

### III. *The Main Results*

The main results of fitting a Cobb-Douglas-type production function to data on per-farm output and input averages for 39 states are summarized in Table 2. Preliminary investigations showed that estimates for different cross sections do not differ significantly and, hence, most of the discussion that follows will be based on results obtained by combining the data from several cross sections and imposing the assumption of constancy of coefficients throughout the 1949-59 period.<sup>4</sup>

<sup>4</sup>Equations comparable to those reported in columns 3-6 of Table 2, but without the time dummies, were computed for each of the three cross sections separately. Using the standard normality and independence assumptions, one could not reject the null hypothesis that the separate estimates for 1949 and 1954 did not differ "significantly" (at conventional significance levels) from the joint estimates for 1949-54. The same was also true for the 1954 and 1959 with 1954-59 comparison. (The computed F statistic is 1.1 for the 1949-54 comparison and 2.0 for the 1954-59 comparison. Given the usual assumptions the "critical" value of the F statistic, with 7 and 64 degrees of freedom, is about 2.3 at the .05 and 3.5 at the .01 significance levels.) The results are somewhat weaker but similar for the over-all comparison of all three separate equations with the pooled (but without time dummies) 1949-54-59

The major findings of the previous study are confirmed by the results of this study. The education of the farm labor force is again a "significant" variable, entering the equation with a coefficient which is not significantly different from that of the labor variable.<sup>5</sup> Thus one can combine both the quantity and quality dimensions of labor into one variable, which simplifies some of the subsequent analysis. Again, this study finds evidence of substantial economies of scale. The sum of the estimated coefficients (excluding those of education, research and extension, and time dummies) is consistently above unity with 1.2 being a reasonable point estimate.<sup>6</sup> Nor is this finding contradicted when an attempt is made to guard against the possibility of simultaneous-equations bias using the method of instrumental variables to estimate the coefficients of the production function (col. 7 of Table 2). In general, the results of using the instrumental variables approach for both the 1954 and 1959 cross sections (the latter results are not reproduced here) differ little from those based on single-equation least-squares procedures.<sup>7</sup>

The main novelty of this study is the introduction of a variable to reflect the contribution of public expenditures on agricultural research and on the dissemination of its results on the level of agricultural productivity in different states. The measure used is quite crude: it is the sum of all the relevant entries in the annual budget of the respective state agricultural experiment stations and extension services. To allow for some lags in the effect of these expenditures, this variable was defined as an average of the flow of expenditures in the previous year and the level six years previously. Thus, the average of 1958 and 1953 is used in the 1959 cross section, the average of 1953 and 1948 is used in the 1954 cross section, and the average of 1948 and

---

equations. (The computed F statistic is now 2.1, while the "critical" value of this statistic, with 14 and 96 degrees of freedom, is about 2.0 at the .05 and 2.4 at the .01 level.) See [3, Ch. 6] for details of such tests.

<sup>5</sup> The computed F statistic for the test of equality of the two coefficients for the 1954-59 cross section is 2.3. The "critical" value of F with 1 and 70 degrees of freedom is at least 4.0, even at the .05 level. The results for other cross sections are similar.

<sup>6</sup> Taking the lower estimate of the sum of the coefficients in column 3 of Table 2, we can construct a test for its difference from unity by computing the variance of this sum. In this case, it is just the sum of the variances plus twice the sum of the covariances of all the relevant coefficients. The standard deviation of the sum of the coefficients is 0.0434. Under the null hypothesis and the standard normality and independence assumptions, the ratio of the difference of the sum from unity to its standard error  $.19715/.0434 = 4.54$  has the "t" distribution with 108 degrees of freedom. The probability of observing a ratio as high as 4.54 if the true sum were equal to unity would be less than one in ten thousand. Thus the excess over unity is "highly significant."

<sup>7</sup> Since lagged inputs are used as instrumental variables, the implicit reduced forms have very high  $R^2$ s, and thus the substitution of a "predicted" for the actual input series (in two-stage least-squares language) makes very little difference.

The equation estimated is linear in the logarithms of the variables (except for the time dummies). The output and input variables are per-farm state averages. A total of 39 "states" is used in each cross section, some of these "states" being a combination of several smaller adjoining states (see footnote 1 for details).

Output equals value of sales, inventory change, home consumption, and government payments. The separate components are deflated in detail by U.S. price indexes with 1949=100.

Land and Buildings: The value of buildings is computed as the product of the percentage of value that is due to buildings and the total value of land and buildings per farm and deflated by an index of building materials prices with 1949=100. "Land" is a constant price volume measure constructed by David Boyne [2], using 1940 relative prices of different categories of land in each state and the changing number of acres in these categories in the subsequent years. It is inflated to add up in 1949 (for the U.S. total) to the total value of land and buildings. The resulting measure of land takes into account quality differences in land at 1940 relative state prices, but does not allow subsequent appreciation due to product price

1945 (since the data for 1943 were not strictly comparable) is used in the 1949 cross section. Given the crudeness of this measure, it is surprising that it is as significant as it is. Also, its coefficient remains remarkably stable when cross sections are added or subtracted, and when other variables are introduced or the measurement and definition of included variables are changed. While the estimated coefficient of R & E may appear to be rather small—a doubling in the level of public R & E expenditures per farm would lead to an increase in output of only about 5 per cent—the implied absolute effect is very large. The average (geometric) public expenditure on R & E during the whole 1949-54-59 period was only about \$32 per farm per year, while the average gross output per farm (in 1949 prices) was \$7,205 per year during the same period. Using 0.059 for the coefficient of

trends and other changes to be reflected in the “quantity” measure. The result is a measure of the *stock* of land and buildings per farm.

**Machinery:** A measure of the stock of machinery is constructed by valuing a relatively detailed list of machines on farms by the average U.S. price for such new machines in 1949, allowing for some regional differences in the average price of a machine, due to regional differences in the average size of machines, where data were available. The result is an estimate of the gross (undepreciated) stock of machines on farms in 1949 prices. This is converted into a flow measure by multiplying it by 0.15 (the fraction that flow is of gross stock under the assumption of an average length of life of 10 years and an 8 per cent rate of interest) and added to the deflated values of gasoline, oil, and other machinery operation and repair expenditures to arrive at an estimate of the total flow of services associated with the use of farm machinery.

**Fertilizer:** weighted plant nutrients. The sum of nitrogen, phosphoric acid, and potash consumption weighted by 1955 relative prices for these ingredients (1.62, .93, and .45 respectively).

**Other:** The sum of deflated expenditures on purchased feed and livestock, interest on the livestock inventory (at 8 per cent), and expenditures on seed and other current inputs not elsewhere classified.

**Labor:** A measure of labor-days-worked constructed by adding together total expenditures on hired workers divided by the average wage rate per day and the number of family workers times the average number of days worked on the farm (constructed by subtracting from 300 the estimated number of days worked off the farm by operators). Additional adjustments were made for operators over 65 years of age (they were entered with a weight of 0.6) and unpaid family workers (who were entered with a weight of 0.65).

**Education:** weighted school years per man (25 years and older in the rural farm population), using 1950 mean incomes for the respective education categories (for all U.S. males) as weights. See [6] for additional details on the construction of this variable.

**Research and Extension:** undeflated sum of total expenditures on research and extension by the respective agricultural experiment stations and extension services based on all sources of funds (including USDA appropriations). Averages for the previous year and five years previously, except for the 1949 cross section where these expenditures are averages for 1948 and 1945.

Time dummies take the value of unity for observations in the specified year and zero for all the other observations.

**I.V.:** coefficients estimated by using the method of instrumental variables, assuming that all the “current” input variables (“other,” fertilizer, and labor) are endogenous, and by using the current wage rate and the lagged values of these inputs from the previous cross section (i.e. at  $t-5$ ) as instrumental variables.

The “sum of the coefficients” excludes the coefficients of the education, research and extension, and time-dummies variables.

R & E (from column 3, Table 2) leads to an estimate of its marginal product of  $.059 \times 7,205/32$  or approximately 13 dollars of output per year for an additional dollar of R & E expenditures per year. This finding implies the fantastically high gross rate of return of about 1300 per cent for social investment in agricultural research and extension. Even if one allows that much of it is the result of research expenditures by private firms (mainly in the agricultural supplies industries),<sup>8</sup> and that, due to our inability to solve the agricultural problem, the social value of additional agricultural output is only about half of its market value, the gross social rate of return to R & E expenditures is still about 300 per cent. This last figure is of the same order of magnitude as a previous estimate (in [4]) of a 35 to 170 per cent *net* social rate of return to agricultural research based on entirely different data and a different approach.

The estimated average "marginal products" of all the inputs in 1949 and 1959 are presented in Table 3. In general, they do not appear to conflict with other information that we have on the economic conditions and economic history of this industry. For the inputs that are measured in units of dollars per year, one would expect marginal productivity coefficients on the order of 1.2, given the previous finding of economies of scale of about this order and the assumption that the marginal products, while not equal, are still proportional to marginal costs.<sup>9</sup> This is, in fact, approximately the order of magnitude of the numbers in columns 1, 4, and 6 of Table 3. The only two columns that seem to imply substantial disequilibrium at both the beginning and the end of the period are the fertilizer and the research and extension columns. A ton of weighted plant nutrients cost about \$250 throughout most of this period, implying a ratio of the marginal product to factor price between 3 and 5. Farmers have not remained idle in the face of such a disequilibrium. Between 1949 and 1959 fertilizer consumption grew at the tremendous rate of 7.4 per cent per year (more than doubling fertilizer consumption during this period) and continued to grow at the rate of 5.6 per cent per year between 1959 and 1962. The estimated equilibrium gap (VMP/factor price) has declined from about 5 in 1949 to 2.7 in 1959 and 2.4 in 1962 (using the estimated 1954-59 coefficient). But even if fertilizer consumption continues to grow at about the same rate, relative to output, as it did during the 1959-1962

<sup>8</sup> Assuming that private expenditures are perfectly correlated with public expenditures and are of about the same order of magnitude (see [4] for some support for the last statement).

<sup>9</sup> If there are economies of scale, the adding-up or product-exhaustion theorem doesn't hold. Factors cannot all be paid their marginal product, since this would overexhaust the available total.

Computed by multiplying the appropriate geometric average output ratio by the respective input coefficient from Table 2 (column 4 for 1949 and column 5 for 1959). The numbers in brackets are a crude translation of the estimated standard errors from Table 2 into comparable units. The units are (from right to left): dollars per dollar (both per year) for columns 1, 4, 6, and 7; dollars per year per dollar or per cent per year for column 2; dollars per weighted plant nutrient ton for column 3; and dollars per day for column 5.

period (4 per cent per year), the disequilibrium is not likely to disappear before the early 1980's unless there are some new price and technological developments. At any rate, the regression estimates confirm the existence of this disequilibrium, while the observed market behavior reflects the producers' attempt to reduce it.

Public research and extension expenditures are, of course, outside the farmers' control (at least directly). Thus there is no obvious way for them to eliminate this disequilibrium except through individual attempts to acquire more of the products of this activity, which are largely free to them (except for the nonnegligible monetary and psychological cost of doing so). But even if we make the fourfold downward adjustment discussed above and also adjust for the decline in farm product prices since 1949 (by 4 per cent), we are still left with a social disequilibrium gap of over 2 (or a *net* social rate of return of more than 100 per cent). Thus, perhaps, we should not be so quick to cut the agricultural research appropriations in our attempt to solve the farm problem.

The education variable is measured in dollars per year that a comparable average education mix would fetch in the nonfarm sector. When detailed adjustments are made to bring the farm and nonfarm labor force measures into comparable units, as in [7], it is found that a ratio of about .7 of farm to urban per capita income is consistent with equal real returns for comparable labor. Thus, a marginal product of about .7 or so, which would be in units of farm dollars per urban dollars, would indicate an approximate equilibrium with respect to this variable. Since the estimated coefficients are higher than that,

though probably not significantly so, there is some indication that the marginal return to quality of labor in agriculture may actually exceed its opportunity cost in the nonagricultural sector.

One of the findings of the previous study was that the estimated labor coefficient appeared to be lower and the coefficient of machinery higher than the coefficients that would be implied by the factor-shares approach. This finding is not confirmed by this study. When the estimated factor shares are adjusted for the difference in the concept of output used in this study and the estimated production function coefficients are divided by their sum (to add up to unity), the two sets of coefficients are quite close to each other, and the differences that remain are not statistically significant. Thus, while the previous findings would have implied a marginal product of labor below the going wage rate, when the estimates in Table 2 are adjusted for economies of scale and for the minor decline in farm-product prices between 1949 and 1959, the resulting marginal product of labor estimates of \$4.80 and \$8.30 per day are not significantly different from the U.S. average wage rate of hired farm workers of \$4.40 and \$6.50 per day in 1949 and 1959 respectively.<sup>10</sup>

If all the variables were measured correctly, the coefficients of the time dummies would be estimates of the rate of "disembodied" technical change (relative to 1949). In practice, however, they also reflect errors of measurement in the average level of variables. Hence, the fact that they are almost never significantly different from zero may be the result of underdeflating some of the input series (or, for example, not deflating the R & E expenditures at all). On the other hand, an attempt has been made to incorporate as many adjustments for quality change as possible into the measurement of inputs and, hence, one might expect that only a very small role would be assigned to disembodied technical change. It would be beyond the scope of this paper to repeat the analysis of sources of growth presented in [6]. But if one uses the estimated coefficients from Table 2 and data on input and output change over time, it is possible to account for *all* of the observed growth in agricultural output without invoking the unexplained concept of (residual) technical change. Table 4 summarizes an analysis of the "residual," which parallels closely the results presented previously in Tables 4 and 7 of [6]. As against the previous study, the current results reduce somewhat the role of economies of scale, increase somewhat the role of education and other input quality change, and

<sup>10</sup> The differences that remain may be due to the lower-than-average quality of the workers (the hired ones) for whom the market price is measured. Actually, about two-thirds of the total work is done by family members, whose average education and also motivation are higher than those of the hired farm labor force.

assign for the first time a substantial role to the previously unmeasured contribution of public investment in agricultural research and extension to the explanation of the growth in the aggregate output of agriculture. Taking items 2c through 2f as what one could have called the "residual" in this study, the total can be divided into three roughly equal parts: the contribution of input quality change (in labor and other inputs), of economies of scale, and of investments in research and extension.

#### IV. Conclusions

"Productivity," "technical change," or the "residual" are usually computed residually, as part of some accounting framework. Because of the nature of the beast, it is impossible to test *accounting* frameworks statistically. One may discuss the "usefulness" of various accounting schemes, as I have done in [6], where I suggest using a framework that *minimizes* the role of the unexplained residual, but the argument eventually reduces itself to aesthetics and research strategy. It is possible, however, to test some of the components of an accounting scheme separately if data which these concepts do not have to fit tautologically are used. The empirical work on aggregate production functions reported here has been motivated by a desire to gather statistical evidence for various theoretically justifiable adjustments to the conventional accounting framework. The study has been designed to investigate whether there is evidence for introducing a

measure of education and a measure of research investment into the accounting scheme for growth and whether there is evidence for relaxing the assumption of constant returns to scale. None of these questions can be answered unequivocally by looking only at one piece of data. They are too interdependent. This is why one must repeat the analysis on different sets of data, some of them being better suited for illuminating one or another aspect of the problem.

In this paper I have reproduced some of the previously reported results on a new set of data. "Education" does belong in the production function, and there do appear to be substantial economies of scale in agriculture. A new variable, public investment in research and extension, is introduced and found to be both "significant" and important as a source of aggregate output growth. Using the estimated coefficients as weights, and the expanded and adjusted list of inputs, one can again account for most of the observed growth without being left with a large unexplained "residual." None of these conclusions is very firmly established, and some may be subject to substantial bias,<sup>11</sup> but the only known way of either confirming or disproving them is the slow and expensive but cumulative process of conducting additional studies of this type on different bodies of data.

<sup>11</sup> The finding of economies of scale is particularly susceptible to bias due to incomplete or incorrect accounting. If not all of the inputs are adjusted for quality differences, and they are not, and if larger size farms tend to use higher quality inputs, then some of what is measured as economies of scale are actually due to differences in the quality of inputs. Also, these economies may be the reflection of discontinuities in the range of available machine sizes with the resultant nonhomogeneity of the production function. In either case, the accounting is still correct, but the interpretation of a particular category is less firm.

##### *Data Sources*

A complete description of the data used in this study will be given in a publication presenting a more extended version of the results of this study. Only the most important adjustments are described below.

Most of the data on output and input by states are taken from USDA, *Farm Income: A Supplement to the Farm Income Situation for July 1961, State Estimates 1949-1960*, Washington, August 1961. Output is defined as the sum of cash receipts from farm marketings, government payments, value of home consumption, and net change in farm inventories. The first item was divided into 12 commodity groups (such as meat animals, dairy products, poultry and eggs, feed crops, food grains, etc.) and each was deflated separately by an appropriate U.S. price index (1949 = 100). In a few cases where one particular commodity accounted for a large fraction of total receipts in a state, the deflation was done on an even finer commodity level. The price indexes used are components of the Prices Received by Farmers Index and were taken from various issues of *Agricultural Prices*. The resulting procedure produced an implicit farm-marketings deflator for each state. This deflator was used in turn to deflate the government payments, value of home consumption, and net inventory change categories.

The following items were also taken from the *Farm Income* publication: Current expenses on (1) feed, (2) livestock, (3) seed, (4) repairs and operation of capital items (excluding buildings), (5) miscellaneous, and (6) hired labor. Unpublished data supplied by the U.S. Department of Agriculture were used to exclude the building component from (4). Each of these components was deflated separately by the appropriate U.S. subindex of the Prices Paid by Farmers Index taken from USDA, *Prices Paid by Farmers . . . , 1910-1960*, Stat. Bull. No. 319; except for (6)—hired labor—which was “deflated” separately by dividing it through by the average wage rate per day paid to hired farm labor in *each* state to arrive at a “days worked” measure. These wage rates and the hourly ones used explicitly as a variable in the regressions summarized in Table 1 were taken from various issues of *Farm Labor*.

The “other” inputs variable was constructed as the sum of items (1), (2), (3), (5) and interest (8 per cent) on the constant price value of livestock and crop inventories on farms. The latter item was estimated by multiplying the physical data on the inventory of different types of livestock and different crops stored on farms by their average 1949 U.S. prices.

The construction of the land and buildings, machinery, and fertilizer variables is described in the notes to Table 2. The data on the inventory of machines on farms come from USDA, *Numbers of Selected Machines and Equipment on Farms*, Stat. Bull. 258, 1960, and the respective volumes of the *Census of Agriculture* for 1949, 1954, and 1959. The prices used to value

this inventory were derived largely from USDA, *Farmers' Expenditures for Motor Vehicles and Machinery . . . 1955*, Stat. Bull. 243, 1959, and converted to 1949 levels by using the appropriate series from the previously cited *Prices Paid* publication. The data on plant-nutrient use by states were taken from various reports of the Soil and Water Conservation Branch of the USDA.

The labor measure, in days, equals

$$D\{N(1 - 0.4A) + 0.65(F - N)\} + HE/W$$

where  $D$  is the estimated average days worked on farms by operators (estimated by subtracting from 300 the calculated average number of days worked off the farm by operators),  $N$  is the number of farms, assumed also to equal the number of farm operators,  $A$  is the fraction of operators above age 65,  $F$  is the total number of family workers,  $N - F$  is thus the estimated number of unpaid family workers (set to zero in the few cases where  $F > N$ ), and  $HE/W$  is the estimated number of hired worker man-days (hired worker expense divided by the wage rate per day).  $N$  and  $F$  are taken from various issues of *Farm Labor*. " $A$ " and the data on off-farm work come from the *Census of Agriculture* volumes for the respective years. The implicit weighting of operators over 65 at 0.6 and of unpaid family workers at 0.65 is the same as in [6] and is based on E. G. Strand and E. O. Heady, *Productivity of Resources Used on Commercial Farms*, USDA Tech. Bull. 1128, November 1955.

The education variable was based on the distribution of the male rural farm population by school years completed taken from the 1950 and 1960 *Census of Population*. These distributions were weighted by the mean U.S. income for males (over 25) in 1950, based on 1950 Census of Population data. See [6] for additional details. 1954 was approximated by a simple interpolation between 1950 and 1960.

The data on research and extension expenditures are taken largely from Dana G. Dalrymple, *State Appropriations for Agricultural Research and Extension*, Mich. State Univ. Department of Ag. Econ., A.E. 852, Dec. 1961 and the annual reports on "Cooperative Extension Work in Agriculture . . ." and "Agricultural Experiment Stations" by the USDA Office of Agricultural Experiment Stations.

All variables, except education, are divided by  $N$  to arrive at per-farm units.

## SHIFTS IN THE COMPOSITION OF DEMAND AND THE INFLATION PROBLEM

*By* W. G. BOWEN AND S. H. MASTERS\*

In recent years a number of persons have suggested that shifts in the composition of demand play a role in the inflationary process. More specifically, the usual hypothesis is that, other things equal, the over-all price level is likely to rise more rapidly, the greater the extent of shifts in the composition of demand. This hypothesis is based on two separate propositions concerning price and wage behavior, one having to do with the shape of supply schedules and the other pertaining to collective bargaining and wage behavior. In brief, the supply-schedule proposition is that there is a ratchet effect, that prices of all kinds are more flexible upwards than downwards; the wage-determination proposition is that "large" increases in wages are likely to occur in rapidly expanding sectors and that these increases will be transmitted, at least in part, to other sectors.<sup>1</sup>

\* The authors are, respectively, associate professor of economics and assistant in research at Princeton University. They are indebted to W. J. Baumol and E. J. Kane for useful comments on an early draft of this paper and to Mrs. Virginia Gebhardt for her computational assistance. They also wish to thank the participants in the Princeton Seminar on Research in Progress, and especially A. Corazzini and R. Gold, for a number of very helpful suggestions.

<sup>1</sup> To elaborate just a bit, for the benefit of readers who have not followed the literature dealing with this topic, the shape-of-the-supply-schedule aspect of the argument asserts that in imperfectly competitive markets decreases in demand are unlikely to result in price reductions, whereas increases in demand may well entail increases in marginal costs and thus price increases. In short, the typical supply schedule is alleged to be horizontal over the range of output below the current output level and to slope upward as capacity output is approached. The greater the extent of shifts in the composition of demand, the greater the upward thrust to the over-all price level imparted by this ratchet-type mechanism. The wage-determination aspect of the argument postulates the following sequence of events: (1) rapid shifts in the composition of demand produce increases in profits in the expanding sectors, which in turn increase union wage demands, lower employer resistance (by raising the cost of strikes), and thus lead to relatively large wage increases in this sector; (2) because of the importance of wage comparisons to unions and companies, these "large" increases in wages will be transmitted (at least in part) to other sectors, with the result that cost schedules in both sectors are shifted upward, assuming that the average wage increase exceeds the average increase in output per man-hour. Finally, it is often assumed that the monetary-fiscal authorities take whatever expansionary actions are necessary to prevent total output and employment from declining as a consequence of these upward shifts in cost schedules. While much can be (and has been) said about the plausibility of these various propositions, this discussion falls outside the scope of our paper.

Charles Schultze, in his Joint Economic Committee paper on the 1955-57 inflation, has supplied what is probably the best-known statement of this general line of reasoning. In addition to developing the main lines of the demand-shift *hypothesis* (as sketched above), he attempted to use this hypothesis as a partial explanation for price behavior during 1955-57 by adding the *assertion* that in fact shifts in the composition of demand were unusually pronounced during this period.<sup>2</sup> To the best of our knowledge, no systematic effort has been made to test this empirical assertion by actually trying to estimate the extent of shifts in the composition of demand from one period to another, let alone to test the underlying demand-shift hypothesis.

It is to the limited task of measuring the extent of shifts in the composition of demand within different periods, and seeing if indeed shifts in the composition of demand were unusually pronounced during the 1955-57 period, that this paper is addressed. We wish to emphasize that we are not testing the validity of the demand-shift hypothesis itself. This hypothesis is, of course, a *ceteris paribus* hypothesis and can be tested properly only in the context of a complete model of the inflationary process. A rigorous test would need to employ multivariate analysis in order to isolate the influence of demand shifts from such other factors as the balance between aggregate demand and supply, the state of money markets, and the wage and price practices of particular groups of unions and firms. We hope that by calling attention to the need for more careful empirical work along this line, by suggesting some simple aggregative measures of demand shifts, and by presenting what we consider to be some interesting differences between periods in the extent of demand shifts, we shall encourage (or provoke) others to do the more extensive type of research that is necessary.<sup>3</sup>

The two main empirical conclusions of this paper can be summarized as follows. First, the 1955-57 period was characterized by shifts in the composition of demand which were well above average in magnitude, compared with other postwar periods, though not extraordinarily large in the sense of being separated from the results for all periods by a wide gulf. Second, we also discovered, as an admittedly accidental by-product of our work, that the period between 1957 and 1963 has been characterized by abnormally small shifts in the composition of demand. If one accepts the demand-shift hypothesis, this last finding has in-

<sup>3</sup> One word of warning is in order: anyone attempting to use multiple regression techniques in a time series analysis is faced with a serious degrees-of-freedom problem if he defines his observation periods in terms of relatively long intervals such as 1955-57. (Our criterion for defining periods is discussed later in this paper.)

interesting implications for the way in which we view the relatively moderate increase in the general price level that has occurred in the more recent period. However, before saying anything more about the meaning of our findings, it is well to describe the measures used and the statistical results.

### *Concepts, Measures, and Methods*

Estimating *ex ante* shifts in the composition of demand on the basis of *ex post* data is not easy. We rely mainly on two simple measures, the first of which is an index of sales dispersion labeled  $I_t$ , which for any given period  $t$  is defined as:

$$(1) \quad I_t = \sum_{i=1}^n |\bar{S}_t - \dot{S}_{it}| W_{it}, \quad \text{where}$$

$\dot{S}_{it}$  = the rate of change of dollar sales in the  $i$ th industry from the beginning to the end of period  $t$ , expressed at an annual rate by the usual compounding formula;

$W_{it}$  = an income-originating weight for the  $i$ th industry, obtained by dividing the income originating in industry  $i$  during period  $t$  by the total income originating in all  $n$  industries during period  $t$ ;

$\bar{S}_t = \sum_{i=1}^n \dot{S}_{it} W_{it}$ , a weighted average of all the individual industry

rates of change of sales.

The reason for using interindustry differences in rates of change of sales to represent interindustry shifts in the composition of demand is that shifts in demand are likely to evoke relative price and relative output responses, both of which are taken into account by the sales measure.<sup>4</sup>

Individual industry deviations from the all-industry average rate of change of sales are multiplied by income-originating weights for two reasons. First, the usual indices of the general price level are, of course, weighted measures, and we can expect at least a rough correspondence between weights of income originating by industry and the weights

<sup>4</sup> We recognize that interindustry differences in sales behavior can result from supply-side changes (especially differing rates of productivity gain) as well as demand-side changes, but there is no simple way to separate the two effects. This is somewhat less troublesome than it might at first seem because interindustry differences in productivity gains can themselves lead to interindustry differences in profits, and thus to the same wage-determination process postulated in the demand-shift model. Edwin Dale has in fact suggested a model of the inflationary process much like the demand-shift model, except that it is differential rates of productivity gain which provide the impetus for upward pressure on the price level. (See Dale's articles in the *New York Times*, March 10, 1957, pp. 1, 54, and May 19, 1957, pp. 1, 48; see also the critique by Fellner, in the "Letters" column of the March 25, 1957 issue.)

attached to various product classes in the construction of these indices. Second, as a general rule, we would expect the indirect price effects that are likely to result from transmission of industry *A*'s wage and cost increases to other industries to be greater, the greater the income originating in industry *A*. Thus, wage increases in the auto and steel industries, for instance, can be expected to have more of a direct effect on the usual price indices and to be more important in influencing other negotiations than wage increases in smaller industries. Ideally, we would have liked to include in our weighting scheme factors which reflect differences among industries in their own wage and price flexibilities in response to demand shifts; but no practical way of devising a suitable set of flexibility factors occurred to us.

Our second measure is nothing more than the weighted standard deviation of the rates-of-change-of-sales set of data, and is defined as:

$$(2) \quad I^* = \sqrt{\sum_{i=1}^n (\bar{S} - S_i)^2 W_{ii}}$$

The squaring operation used in the calculation of  $I^*$ , in effect assigns a more than proportionate weight to extreme deviations from the all-industry average rate of change of sales, and whether one prefers  $I^*$  or  $I_s$  depends on whether or not one's theory of wage-setting and pricing leads him to favor this greater emphasis on extreme values. We do not tend to prefer  $I^*$ , because we are inclined to think that downward rigidities and upward flexibilities are likely to have a more than proportionate impact within industries growing or declining at an unusual pace. Also, transmission effects may well bear a nonlinear relationship to the absolute deviations from the all-industry average rate of change of sales. We do not wish, however, to put much emphasis on this nonlinearity premise, and so we present both the  $I_s$  and the  $I^*$  measures.

Let us turn now from the measures themselves to the details of our computational procedures. Department of Commerce data for twenty-one two-digit industries are used as the basic sales data.<sup>5</sup> Indices of interindustry shifts are calculated for the six time periods shown in Table 1 (p. 979). As the reader can confirm by looking at a chart of the Federal Reserve Production Index, all of the terminal dates represent relative production peaks—no months of pronounced expansion or contraction in aggregate industrial production are used to mark off periods.<sup>6</sup> This approach to the dating of the periods is necessary be-

<sup>5</sup> A list of the 21 industries and exact references to data sources are included in Appendix A.

<sup>6</sup> The one possible exception to this rule is the terminal month for the July 1957-

cause industries differ significantly in their degree of sensitivity to cyclical swings in business activity. To take an extreme example, a period which started at a business-cycle peak and ended at a trough would exhibit pronounced shifts in output and sales composition due to cyclical considerations alone. We have tried to choose our terminal dates in such a way as to prevent cyclical influences from dominating interperiod differences in the dispersion indices.

### *Results and Interpretations*

Results for both measures are presented in Table 1. Period 5 (September 1955-July 1957) is the Schultze period, and we see that the  $I_s$  measure does take on its highest value during this period and the  $I^*$  measure its second highest value. Thus, if we pool all our observations (implicitly assigning equal stature to both measures and assuming that comparisons among all six periods are equally meaningful), we conclude that the Schultze period was characterized by shifts in the composition of demand which were well above average in magnitude.

A closer inspection of Table 1 suggests, however, that it may be somewhat misleading to treat all six periods as if they were observations drawn from the same universe, and that the six periods should be divided into two broad categories on the basis of the timing of postwar recessions. We know that periods (1), (3), and (5) were plateau-like periods characterized by relatively low unemployment and the absence of sharp downturns in economic activity; periods (2), (4), and (6) spanned recessions. Looking at the results in Table 1 from this perspective, we see that both of our measures of dispersion take on lower

March 1963 period. March 1963 cannot be considered a true production peak in light of the steady expansion in output that has occurred since then.

values in each of the three periods spanning recessions than in each of the three nonrecession periods. We have no firm explanation for this persistent pattern,<sup>7</sup> but its existence does suggest that perhaps it is more meaningful to compare 1955-57 with only the two other non-recession periods. When we limit the comparison in this way, the Schultze period still appears to be somewhat above average in terms of degree of sales dispersion, but the range among periods is reduced considerably. (It should be noted that the nonrecession period which vies with September 1955-July 1957 for the top ranking is January 1947-July 1948, a period when reconversion from a wartime to a peacetime economy was still under way.)

A stronger case can be made for September 1955-July 1957 as a nonrecession period characterized by unusually rapid shifts in the composition of demand if we take account of differences among periods in the over-all rate of increase in economic activity and work with *relative* measures of dispersion (measures which in effect deflate the absolute degree of dispersion among industries by the all-industry average rate of change in economic activity). However, finding a relative measure which makes sense in terms of one's a priori notions of wage and price behavior is difficult, and we have deferred a discussion of this matter to Appendix B.

We come now to our findings concerning the more recent period (period [6], measured from July 1957-March 1963). Here the two absolute measures of dispersion (and the relative measures as well) give identical ordinal results—shifts in the composition of demand were much smaller during this period than during any of the other postwar periods. We have been asked by several people who read an earlier draft of this paper if breaking this rather long period at May 1960 (the peak month following the 1959 recession) would affect these results. Additional calculations have been made for the two subperiods July 1957-May 1960 and May 1960-March 1963, and the results are entirely consistent with the results for the recent period taken as a whole. For both measures, the values for *each* of these two subperiods are smaller than the values for all five of the pre-July 1957 periods.

<sup>7</sup> As explained above, we tried to date our periods so as to avoid reflecting direct cyclical influences on dispersion in our measures. And there is no reason to expect (unsystematic) errors in our dating decisions to cause the nonrecession periods to show either more or less dispersion than the recession periods. The only hypothesis we have been able to develop is that consumers and businesses are more likely to rearrange patterns of expenditures when times are relatively good and there is a (previously uncommitted) margin above old expenditures to "play with" than when there is substantial unemployment. This is analogous to the argument that the federal government is fairly well committed to maintain old expenditures and that it is new receipts which offer the real opportunity for changing the over-all balance among different types of expenditures.

As we admitted at the beginning of this paper, this result came as something of a surprise to us; and we suspect that it may surprise others as well, since we have found no statements calling attention to the rather remarkable degree of uniformity in interindustry sales trends that has characterized the period since mid-1957.

From the standpoint of the inflation issue, the interpretation of this finding depends, of course, on whether one accepts the demand-shift hypothesis. While we do not pretend to have tested the hypothesis itself, we are inclined, on the basis of the a priori plausibility of the hypothesis and on the basis of the lack of contradictory evidence, to assume that it has some validity. Given this viewpoint, the data suggest that one reason for the relatively good record of price stability in recent years may be the low magnitude of the secular shifts in the composition of demand over the course of this period. Persistent high unemployment and the size of the "gap" between actual and potential GNP were, we are confident, of much greater importance in holding prices down—but there is no reason that these usual macroeconomic variables need to be given exclusive billing.

Whether, in future years, shifts in the composition of demand will again become more pronounced is hard to say. However, there is no obvious reason for thinking that 1957 was a kind of watershed, marking off past periods of relatively large shifts in demand from new periods of relatively small shifts. The factors determining demand shifts comprise such a varied list—changes in tastes, demographic trends, and the level and distribution of income—that the presumption would seem to be in favor of some return to degrees of sales dispersion characteristic of past periods. And there is also the likelihood that further corrections in our balance-of-payments situation will necessitate resource reallocations among industries. If the measures of dispersion do again take on higher values, then the demand-shift inflation model implies (*ceteris paribus*, of course) that inflation may become more of a problem than the record of price behavior since 1957 suggests.

1. The sales data were taken from the *Survey of Current Business*, U.S. Department of Commerce, Office of Business & Economics. The output data (discussed in Appendix B) were taken from *Industrial Production, 1959 Revision*, Board of Governors of the Federal Reserve System, Washington, pp. S-124–S-135.

2. Separate rates of change of sales and output were calculated for the following 21 industries:

Food & kindred products  
Textile-mill products

Tobacco manufacturers  
 Apparel & other finished fabric products  
 Paper & allied products  
 Printing, publishing & allied industries  
 Chemicals & allied products  
 Products of petroleum & coal  
 Rubber products  
 Leather & leather products  
 Stone, clay & glass products  
 Primary metal industries  
 Fabricated metal products, including ordnance  
 Instruments  
 Miscellaneous manufacturing  
 Machinery, except electrical  
 Electrical machinery  
 Transportation equipment, except automobiles  
 Automobiles & automobile equipment  
 Lumber & products  
 Furniture & fixtures.

3. Each rate of change of sales,  $\dot{S}_{it}$ , was expressed at an annual rate by use of the expressions  $S_T = S_I(1 + \dot{S}_{it})^T$  where  $S_T$  = sales of the  $i$ th industry at the end of period  $t$ ,  $S_I$  = sales at the start of the period, and  $T$  = length of period  $t$  (in years).

4. The income-originating data (used to construct the weights) were compiled from *U. S. Income and Output*, U.S. Department of Commerce, Office of Business Economics, pp. 130-131, and *Survey of Current Business*, July 1962 and 1963, U. S. Department of Commerce, Office of Business Economics. These income-originating data are annual averages, and so the periods of the weights do not correspond precisely to the periods of the sales and output data. The pairings are shown below:

### B. The Use of Relative Measures

There are reasons for thinking that the rate of change of total sales might have an important effect on the demand-shift inflationary process. First, for a given degree of sales dispersion, more firms are likely to have experienced

absolute declines in sales, the smaller is the increase in the over-all sales level. We associate a sales decline with a downward shift in the firm's demand curve, and the demand-shift theory postulates especially strong wage and price rigidities in the face of absolute declines in demand. Therefore, the smaller is the increase in total sales,  $\bar{S}$ , the greater effect should a given degree of dispersion have on the price level.

Secondly, if a given degree of dispersion results in a given pattern of absolute changes in wage differentials among industries (before transmission effects), and if the change in the general wage level that would have occurred apart from dispersion considerations is positively related to the rate of increase of total sales, then the relative changes in wage differentials will be greater, the smaller is the increase in total sales. And changes in relative wage differentials may be what is most important in determining transmission wage effects.

On the basis of the above reasoning, we tried using "relative" measures of dispersion:  $I_s/\bar{S}$  and  $I^*/\bar{S}$ . We achieved no systematic results and, after further consideration of the full workings of the demand-shift mechanism, concluded that we were introducing perverse feedback effects. Interperiod differences in  $\bar{S}$  are themselves, in part, a result of interperiod differences in the rate of increase in the general price level and therefore of the strength of the inflationary process generated by the initial pattern of demand shifts. The nature of this difficulty is discussed more rigorously in a mimeographed paper which we shall be glad to send to anyone interested in pursuing this matter. There it is demonstrated that using scales in both the numerator and denominator is likely to result in a measure which will have the undesirable property of indicating a smaller degree of dispersion, the more "successful" was a given initial change in the composition of demand in producing a rise in the general price level.<sup>8</sup>

To cope with this feedback problem we divided  $I_s$  and  $I^*$  by the rate of change of output,  $\bar{O}$ , instead of by  $\bar{S}$ . This gives us relative measures which are free of serious feedback effects.<sup>9</sup>

Turning now to the data, the important point is that in the Schultze period  $\bar{O}$  was remarkably low. Between September 1955-July 1957,  $\bar{O}$  was 1.41, compared with values of 4.67 for January 1947-July 1948 and 5.91 for March 1951-July 1953. When we divide by  $\bar{O}$ , both of our measures  $I_s/\bar{O}$  and  $I^*/\bar{O}$  take on by far their highest values in the September 1955-July 1957 period.<sup>10</sup>

<sup>8</sup> Some feedback effects may be present even in our  $I_s$  and  $I^*$  measures. No such effect occurs, however, if we use output data instead of sales in our measures. Separate calculations were made using output data and the results were very similar to those using  $I_s$  and  $I^*$ , so we are not very concerned about feedback here. Also, it is encouraging to see that an independent set of data produces consistent results.

<sup>9</sup> Using sales in the numerator and output in the denominator does produce a kind of "bastard" measure, and so we also made calculations using output in both the numerator and denominator. Again, there were no significant differences in results.

<sup>10</sup> Using the  $I_s/\bar{O}$  measure, the actual value for the Schultze period is 3.79, compared with 1.06 (period 1), .62 (period 2), .81 (period 3), 1.08 (period 4), and .50 (period 6).

Our second main empirical result—that shifts in the composition of demand have been very small during the post-1957 period—is unaffected by the use of the relative measure. All of the various measures used in this paper take on their lowest values during this period.

There is one major difficulty with the relative measure, which accounts for our decision to relegate the discussion of these results to this appendix. We now suspect that dividing by  $\bar{\sigma}$  overcompensates for the “relative” as opposed to the “absolute” effects of dispersion. To illustrate the problem by an extreme example, if the average increase in output were 1.0 per cent in period  $X$  and .1 per cent in period  $Y$ , and if the absolute degree of dispersion were the same in the two periods (say 2.0 per cent), the relative measure would take on a value of 2.0 for period  $X$  and 20.0 for period  $Y$ . This is what happens, to a lesser extent, in the case of the Schultze period (which is analogous to period  $Y$ ) when we use the relative measure. Taking some root of  $\bar{\sigma}$  might help meet this difficulty, but how would one determine which root? Our conclusion is that, until this question is answered, the absolute measures should be given main emphasis (and are therefore presented in the body of this paper). At the same time, we think that the relative measures, and the general results they give, are of some help in the job of interpretation.

# LONG-TERM UNEMPLOYMENT, THE STRUCTURAL HYPOTHESIS, AND PUBLIC POLICY

By N. J. SIMLER\*

To submit the rise-in-structural-unemployment hypothesis to yet another test may strike some as pretty much like subjecting an apparently dead horse to one last thumping. But the fact is that not all versions of the argument have been given the attention they deserve. In particular, it appears that the rise in the rates of long-term and very-long-term unemployment since 1957 cannot be satisfactorily accounted for or explained by the rise in the over-all unemployment rate. If, upon analysis, this turns out to be the case, it may suggest to some the presence of some kind of underlying structural change. After briefly summarizing the main lines of attack on the structural hypothesis that have appeared so far, this paper seeks to identify the principal factors behind the increase in long-term unemployment rates, to set forth a theory of long-duration unemployment and, finally, to draw certain conclusions respecting public policy.

## I. *Criticisms of the Structural Hypothesis*

Attempts to explain the higher unemployment rates that have characterized the economy since the mid-1950's have centered around two alternative hypotheses. (The Council of Economic Advisers [8] [11, pp. 40-56] [18, pp. 1751-69], along with other proponents of the inadequate-aggregate-demand hypothesis, maintains that the rise in unemployment rates has been due simply to the failure of the rate of growth of final demand for goods and services to keep pace with the rate of growth in potential supply made possible by continuing increases in productivity and in the stocks of productive resources. In other words, a "gap" has emerged between potential and actual output as the annual increment in the number of job opportunities has been insufficient to absorb the yearly increase in the number of job seekers. Accordingly, higher unemployment rates are taken to mean that the economy has departed from a position of full employment.)

On the other hand, proponents of the rise-in-structural-unemployment hypothesis, such as Thomas Curtis [1], Walter Fackler [17, pp.

\* The author is associate professor of economics at the University of Minnesota. He would like to thank O. H. Brownlee, Edward Kalachek, John Kareken, George Perry, and Seymour Wolfbein for critical comment on this paper, without committing them to any of the argument.

44-56], and Charles Killingsworth [18, pp. 1461-83], appear to be saying that the rise in unemployment rates has taken place despite the presence of a generally adequate level of aggregate demand and a tolerably sufficient number of job opportunities. (Unlike the demand hypothesis, the structural hypothesis has taken several forms, but in each instance it seems to have been implicitly or explicitly assumed that the increase in the number of unemployed workers has been accompanied by an approximately equal increase in number of unfilled jobs. Accordingly, the economy is believed to have remained roughly in a full-employment position, although this is associated with a higher rate of unemployment than before. It is argued that what has happened is that structural changes have occurred which have increased labor market frictions, led to greater imbalances between labor demands and labor supplies, and thus have made markets for labor function less efficiently than before. Each of the variants of the structural hypothesis has come under attack. What follows is a brief summary of these critiques.

1. The structural hypothesis has failed the job-vacancies test, at least on the basis of the National Industrial Conference Board's index of the number of help-wanted advertisements. (If structural change has accounted for the rise in unemployment rates after 1955-57, then it would have to be true that the change in the number and composition of unfilled jobs has paralleled the change in the level and composition of unemployment.) Abstracting from compositional changes, a decrease in the number of job vacancies relative to the number of unemployed persons would imply a shortage of jobs and to this extent would convert the problem into one stemming from inadequate aggregate demand. It turns out that the NICB index, even if it is not adjusted to take account of the growth in the labor force, was actually lower in 1960 and 1962 (years of 5.6 per cent unemployment) than it was in 1955-57 (years of 4.2-4.4 per cent unemployment).<sup>1</sup> If this index were a comprehensive and complete measure of the number of job vacancies, the failure of the structural hypothesis to meet this test would have established a presumptive case against it. But the NICB index does not really measure the number of job vacancies; it only measures the number of help-wanted ads in the classified-ad sections of a selected leading newspaper in each of 33 major labor market areas, which in the mid-1950's accounted for 44 per cent of total nonfarm employment [10, pp. 2-3].

<sup>1</sup> The adjusted NICB index (1957 = 100) averaged about 107 in the 1955-57 period and fell to 91 and 95 in 1960 and 1962, respectively. If the structural hypothesis were correct, one would have expected the index to have risen to the neighborhood of 146 in 1960 and 149 in 1962, in order for it to have paralleled the increase in the number of unemployed persons. The unadjusted index averaged about 106 in 1955-57 and fell to 94 and 100 in 1960 and 1962, respectively; but one would have expected it to have risen to the vicinity of 144 in 1960 and 147 in 1962. Computed from data in [10, Appendix Table 1, p. 41] [15, Table 1, p. 24] [16 Table A-1, p. 195].

Hence, the results of any test based on it can only be considered indicative, not conclusive; and so other tests have had to be devised.

2. (If the structural hypothesis that relative declines in demand for blue-collar and goods-producing workers have been an independent source of higher unemployment rates were in fact correct, then observed unemployment rates in the 1958-63 period in specific, "technologically vulnerable" [18, p. 1758] blue-collar occupations and goods-producing industries should have been systematically higher than what one would have expected on the basis of the 1947-57 experience.) But the Kalachek regressions [8, pp. 97-101] [9, pp. 49-71] [14] [18, pp. 1756-59], in which unemployment rates sector by sector are regressed against the over-all unemployment rate in the earlier period, show no systematic tendency to underpredict the specific sector rates in the later period and, in fact, tend to overpredict these rates.<sup>2</sup>

3. Alternatively, if the structural hypothesis that shifts in the geographic composition of labor demands have been an independent source of higher unemployment rates were in fact correct, then the geographic distribution of unemployment should have been more concentrated in 1960 than it was in 1950. But the studies by Denison [2] [3] and Eckstein [5, pp. 119-23] show that, in fact, the opposite has occurred and that the distribution of unemployment by metropolitan areas, states, and regions was less concentrated in 1960 than it was in 1950. Using different methods, the Kalachek-Denison-Eckstein findings have recently been confirmed by Gallaway [6].

4. Finally, if the structural hypothesis that shifts in the composition of unemployment in the direction of those groups in the labor force with characteristically high unemployment rates (teenagers, nonwhites, and unskilled or uneducated or inexperienced workers) have been an independent source of higher unemployment rates were in fact correct, then the relative unemployment rates of these disadvantaged groups, when weighted by their contribution to the total labor force, should have been higher in 1962 or 1963 than they were in the mid-1950's. But the Gordon study [7] demonstrates that, in fact, the opposite has occurred and that the concentration of unemployment among the above-mentioned groups (except for first-job seekers) has decreased. Using different methods, conclusions similar to those of Gordon had been reached in an earlier study by the Council of Economic Advisers [13, pp. 378-92].

## II. Long-Term Unemployment

Since structural unemployment may be considered an extreme form of frictional unemployment, it should also be revealed by longer spells

<sup>2</sup> Kalachek's work was done while he was a member of the staff of the Joint Economic Committee and, later, the staff of the Council of Economic Advisers.

of unemployment in particular occupations, industries, and areas [11, p. 45]. A partial test of the hypothesis that the rise in unemployment rates since 1957 has been due to structural change can be devised using data relating to long-term unemployment in the economy as a whole. If the structural hypothesis is correct, then observed long-term unemployment rates in the 1958-63 period should be systematically higher than what one would expect on the basis of the 1947-57 experience. )

The Department of Labor defines long-term unemployment as a spell of unemployment lasting 15 weeks or longer. In any given year, the ratio of the number of long-term unemployed persons to the civilian labor force measures the long-term unemployment rate ( $U_L$ ) for that year.  $U_L$  averaged 0.78 per cent in the 1947-57 period and 1.69 per cent in the 1958-63 period, an increase of 117 per cent. At the same time, the over-all unemployment rate ( $U_t$ ) increased from an average of 4.25 per cent to an average of 5.98 per cent, or by only 41 per cent. Thus, the increase in  $U_L$  was almost three times as great as the increase in  $U_t$ .

A simple linear regression of  $U_L$  on  $U_t$  for the 1947-57 period yields the following equation:<sup>3</sup>

$$(1) \quad U_L = -0.589 + 0.323U_t, \\ (0.174) \quad (0.0399)$$

<sup>3</sup> The data for this and all subsequent regressions are contained in Table 1.

where  $\bar{R}^2=0.866$  and  $\bar{S}=0.126$ . When equation (1) is used to predict  $U_L$  in the 1958-63 period, the result is a systematic underprediction of the actual  $U_L$ 's. The deviations of the actual from the predicted  $U_L$ 's are all positive and are fairly large. (See Table 2.)

This test cannot be considered decisive for it is clear that those who comprise the long-term unemployed in any given year need not have become unemployed during that year but could have become so in the immediately preceding year, or even longer ago than that. That is, it is reasonable to suppose that this year's long-term unemployment rate

depends not only on this year's over-all unemployment rate, but also on (at least) last year's. A multiple linear regression of  $U_L$  on  $U_t$  and  $U_{t-1}$  for the 1947-57 period yields the following equation:

$$(2) \quad U_L = -0.826 + 0.315U_t + 0.0641U_{t-1},$$

(0.206) (0.0362) (0.0362)

where  $\bar{R}^2=0.891$  and  $\bar{S}=0.113$ . However, when equation (2) is used to predict the 1958-63  $U_L$ 's, the result is again a systematic underprediction of the actual  $U_L$ 's, although the residuals are somewhat smaller. (See Table 2.)

Equations (1) and (2) give support to the structural hypothesis. But examination of the residuals from both regression lines in the 1947-57 period suggests that the rise in the long-term unemployment rate relative to the over-all unemployment rate may have taken place gradually

and cumulatively over time, rather than having occurred abruptly after 1957. A multiple linear regression of  $U_L$  on  $U_t$ ,  $U_{t-1}$ , and time ( $t$ ) for the 1947-57 period yields the following equation:

$$(3) \quad U_L = -0.841 + 0.316U_t + 0.0662U_{t-1} + 0.0193t, \\ (0.171) \quad (0.0301) \quad (0.0301) \quad (0.00899)$$

where  $\bar{R}^2=0.926$ ,  $\bar{S}=0.0942$ , and  $t_{1952}=0$ , and where each net regression coefficient is statistically significant. (Now when equation (3) is used to predict the 1958-63  $U_L$ 's, there is no longer a systematic tendency to underpredict the actual  $U_L$ 's. The latter are scattered above, below, and virtually on the regression line, and four of them are within one standard error of the regression line. (See Table 2.)

This analysis reveals that time has been a statistically significant factor underlying the rise in the long-term unemployment rate. The problem is to find a variable that might be related to the long-term unemployment rate and for which time might be a proxy. One such variable is the proportion of older workers (defined as those of age 45 and over) in the civilian labor force. This proportion has been increasing. For example, in 1947 older workers constituted 34.2 per cent of the civilian labor force; in 1952, 36.4 per cent; and in 1957, 38.1 per cent.) In fact, a simple linear regression of this proportion ( $L_{45}$ ) on time for the 1947-57 period yields the following equation:

$$(4) \quad L_{45} = 36.221 + 0.438t, \\ (0.0602) \quad (0.0190)$$

where  $\bar{R}^2=0.981$ ,  $\bar{S}=0.200$ , and  $t_{1952}=0$ . At the same time, there is a rather pronounced tendency for older workers to remain unemployed for longer periods of time than younger workers. For example, in 1957 the ratio of the long-term unemployment rate for persons who were 45 years of age and over to the over-all unemployment rate in that age group was 0.27; in the 25-44 age group the corresponding ratio was 0.18; and in the 18-24 age group it was 0.14. Similarly, in 1960 the ratios were 0.32, 0.24, and 0.20, respectively; and in 1962 they were 0.38, 0.28, and 0.22, respectively.<sup>4</sup> Hence, the observed values of  $L_{45}$  may be substituted for  $t$  in equation (3).

(A multiple linear regression of  $U_L$  on  $U_t$ ,  $U_{t-1}$ , and  $L_{45}$  for the 1947-57 period yields the following equation:

$$(5) \quad U_L = -2.575 + 0.322U_t + 0.0684U_{t-1} + 0.0470L_{45}, \\ (0.743) \quad (0.0288) \quad (0.0287) \quad (0.0195)$$

<sup>4</sup> The ratios in this paragraph were computed from data in [16, Tables A-1, A-5, A-8, A-13, pp. 195-203]. The tendency for older workers to remain unemployed for longer periods than younger workers is also borne out by data from other countries. See [12, pp. 60-64].

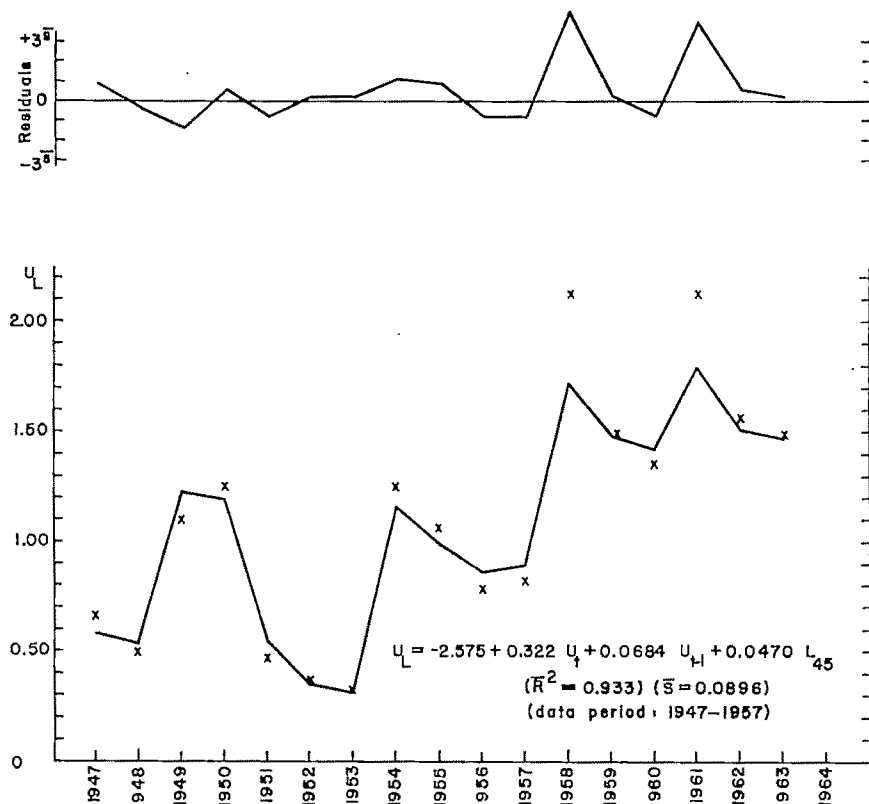

FIGURE 1

where  $\bar{R}^2 = 0.933$  and  $\bar{S} = 0.0896$ , and where each net regression coefficient is statistically significant. When equation (5) is used to predict the 1958-63  $U_L$ 's, there is again no systematic tendency to underpredict the actual  $U_L$ 's. The latter are found above, below, and virtually on the regression line. While four of the actual  $U_L$ 's lie well within one standard error of the regression line, those for the two recession years are outside three standard errors.<sup>5</sup> Figure 1 shows the actual and predicted  $U_L$ 's, together with the residuals, for the period since 1947.

<sup>5</sup> The fact that the regression equation underpredicts by a wide margin the actual  $U_L$ 's in 1958 and 1961 is probably due in some part to the fact that annual, rather than quarterly or monthly, data are used. When a recession trough occurs early in the year, as was the case in both 1958 and 1961, the (annual) average levels of both over-all unemployment and long-term unemployment will tend to be higher than they would have been had the trough occurred late in the year. The reason is that it takes less time to increase unemployment than it does to reduce it. While the ratio of the predicted  $U_L$  to the actual  $U_L$  will be unaffected by the timing of the trough, the ratio of the actual  $U_L$  to the actual  $U_t$  will tend to be the greater, the earlier the trough occurs in the year, and the smaller, the later it occurs. This means that, other things equal, years with early troughs will tend to have positive deviations of the actual from the predicted  $U_L$ , those with late troughs, negative deviations, and those with in-

III. *Very-Long-Term Unemployment*

The analysis thus far has isolated the factors underlying the secular increase in the percentage of the labor force unemployed for 15 weeks or longer. However, the data on long-term unemployment make it possible to compute not only the long-term unemployment rate ( $U_L$ ) but also the very-long-term unemployment rate ( $U_{LL}$ ), where very-long-term unemployment is defined as a spell of unemployment lasting 27 weeks or longer. In this section we shall examine the behavior of  $U_{LL}$  in the 1958-63 period to see whether it conforms to what one would have expected on the basis of the 1947-57 experience.

$U_{LL}$  has increased much faster between the two periods than  $U_L$ .  $U_{LL}$  averaged 0.33 per cent in the 1947-57 period and 0.85 per cent in the 1958-63 period, an increase of 158 per cent; whereas the corresponding increase in  $U_L$  was 117 per cent. It will be recalled that over the same span  $U_t$  increased by only 41 per cent, from an average of 4.25 per cent to an average of 5.98 per cent. Thus, the increase in  $U_{LL}$  was almost four times as great as the increase in  $U_t$ .

A simple linear regression of  $U_{LL}$  on  $U_t$  for the 1947-57 period yields the following equation

$$(6) \quad U_{LL} = -0.238 + 0.133U_t, \\ (0.118) \quad (0.0270)$$

where  $\bar{R}^2 = 0.699$  and  $\bar{S} = 0.0854$ . When equation (6) is used to predict  $U_{LL}$  in the 1958-63 period, the result is a systematic underprediction of the actual  $U_{LL}$ 's. The deviations of the actual from the predicted  $U_{LL}$ 's are all positive and are almost as large as those for  $U_L$  in equation (1). Since  $U_{LL}$  is by definition smaller than  $U_L$ , this means that the tendency toward underprediction in equation (6) is relatively more pronounced than that in equation (1). (See Table 2.)

Despite the stronger indications of the presence of structural change, the grounds for considering this test as decisive are weaker than before. If this year's long-term unemployment rate depends not only on this year's over-all unemployment rate but also on last year's (as has been shown), then surely this year's very-long-term unemployment rate depends even more importantly on last year's over-all unemployment rate. A multiple linear regression of  $U_{LL}$  on  $U_t$  and  $U_{t-1}$  for the 1947-57 period yields the following equation:

$$(7) \quad U_{LL} = -0.455 + 0.125U_t + 0.0589U_{t-1}, \\ (0.114) \quad (0.0201) \quad (0.0201)$$

---

between troughs will tend to have residuals which are closer to zero than those of the others. Roughly speaking, this is actually the case. The residuals for the four recession years are: 1949 (October trough), -0.12; 1954 (August trough), +0.10; 1958 (April trough), +0.40; and 1961 (February trough), +0.35.

where  $\bar{R}^2=0.836$  and  $\bar{S}=0.0628$ . But when equation (7) is used to predict the 1958-63  $U_{LL}$ 's, the result is still a systematic underprediction of the actual  $U_{LL}$ 's. Again, the residuals are of about the same order of magnitude as those for  $U_L$  in equation (2), and so here, too, the tendency toward underprediction is relatively more pronounced than it was in equation (2). (See Table 2.)

Thus, equations (6) and (7) give stronger support to the structural hypothesis than do equations (1) and (2). To test the proposition that the rise in the very-long-term rate of unemployment relative to the over-all rate may have been a gradual and cumulative development related to the increasing proportion of older workers in the civilian labor force, we may employ a multiple linear regression of  $U_{LL}$  on  $U_t$ ,  $U_{t-1}$ , and  $L_{46}$ . For the period 1947-57 this yields the following equation:

$$(8) \quad U_{LL} = -1.454 + 0.129U_t + 0.0614U_{t-1} + 0.0268L_{46},$$

$$(0.402) \quad (0.0155) \quad (0.0155) \quad (0.0105)$$

where  $\bar{R}^2=0.903$  and  $\bar{S}=0.0484$ , and where each net regression coefficient is statistically significant. However, when equation (8) is used to predict the 1958-63  $U_{LL}$ 's, the results are somewhat different from those obtained when equation (5) was used to predict the 1958-63  $U_L$ 's. Whereas the actual  $U_L$ 's had a tendency to fall above, below, and virtually on the regression line, the actual  $U_{LL}$ 's tend (with one exception) to lie above the regression line. Moreover, the  $U_{LL}$  residuals tend to be larger than the  $U_L$  residuals. Only one of the actual  $U_{LL}$ 's lies within one standard error of the regression line and three others are either barely within or just outside two standard errors, while those for the two recession years lie well outside three standard errors.<sup>6</sup> Figure 2 shows the actual and predicted  $U_{LL}$ 's, together with the residuals, for the period since 1947.

#### IV. *A Theory of Long-Duration Unemployment*

The preceding analysis has identified the secular increase in the proportion of older workers in the civilian labor force as a "structural" change underlying the secular increase in long-term unemployment rates. But like the lagged unemployment rate, it is statistically significant but of relatively little quantitative importance. In addition, the influence of  $L_{46}$  can be seen to have waned since 1957. Equation (4) implies that between 1947 and 1957 the trend rate of increase of  $L_{46}$  was 1.1 per cent per year; but between 1958 and 1963 the data show that it grew at a trend rate of only 0.2 per cent per year. And on the basis of

<sup>6</sup> See the preceding footnote for an explanation of the large positive residuals in 1958 and 1961. Here, the residuals for the four recession years conform somewhat more closely to the expected pattern than the later trough, the smaller the positive deviation of the actual from the predicted  $U_{LL}$ : 1949, -0.07; 1954, +0.05; 1958, +0.25; and 1961, +0.32.

the interim revised projections of population, total labor force, and labor force participation rates, it seems reasonable to expect this leveling-off trend to continue through the decade of the 1960's, after which time  $L_{45}$  should begin to decrease and by 1975 approach its 1955-57 level.<sup>7</sup>

If we assume that, during the course of the next few years or so,  $\bar{U}(=U_t=U_{t-1})$  and  $\bar{L}(=L_{45})$  stabilize in the neighborhood of 4 per cent

<sup>7</sup> The proportion of older workers in the civilian labor force ( $L_{45}$ ) varies directly with (1) the ratio of the population 45 years of age and over to the total population 14 years of age and over ( $P_{45}$ ) and (2) the labor force participation rate of persons 45 years of age and over ( $R_{45}$ ), and inversely with (3) the labor force participation rate of persons 14 years of age and over ( $R_{14}$ ) and (4) the ratio of the civilian labor force to the total labor force ( $F$ ). That is,  $L_{45} = (P_{45})(R_{45})(1/R_{14})(1/F)$ . On the assumption that the armed forces continue to comprise the same percentage of the civilian labor force as they have in the past six years (3.725 per cent, on the average), so that  $F = 0.9641$ , the interim revised population and labor force

and 40 per cent, respectively, then equation (5) implies a  $U_L$  of 0.87 per cent, or about 695,000 persons out of an expected civilian labor force of about 80 million. Under the same conditions, equation (8) implies a  $U_{LL}$  of 0.38 per cent, or about 305,000 persons. Equation (5) also implies that a reduction in  $U_L$  of one percentage point requires a decrease of 2.6 percentage points in  $\bar{U}$  or 21.3 percentage points in  $\bar{L}$ , or some combination of the two. Similarly, equation (8) implies that a reduction of one percentage point in  $U_{LL}$  requires a decrease of 5.3 percentage points in  $\bar{U}$  or 37.3 percentage points in  $\bar{L}$ , or some combination of the two. For  $\bar{L}=40$  per cent, this means that  $U_L$  will approach zero as  $\bar{U}$  approaches 1.8 per cent and that  $U_{LL}$  will approach zero as  $\bar{U}$  approaches 2.0 per cent. If  $\bar{U}$  were stabilized in the neighborhood of 2 per cent, then unemployment would presumably be the result of normal labor turnover. Its duration would be relatively short, since it would only involve locating a new job at a time when job opportunities were relatively abundant. In other words, all unemployment would be frictional unemployment.<sup>8</sup>

The preceding analysis has also pointed up a shift in the relationship between  $U_L$  and  $U_{LL}$ , particularly since 1957. To be more specific, regressions of  $U_{LL}$  on  $U_L$  for the 1947-57 and 1958-63 periods yield the following results:

$$(9) \quad U_{LL} = -0.0183 + 0.441U_L, \\ (0.0281) \quad (0.0331)$$

projections contained in [16, Table E-2, p. 242] yield the following values of  $L_{45}$  for 1970 and 1975:

$$L_{45}(1970) = (0.4141)(0.5234) \left( \frac{1}{0.5696} \right) \left( \frac{1}{0.9641} \right) = 0.3946 = 39.46 \text{ per cent};$$

$$L_{45}(1975) = (0.4051)(0.5173) \left( \frac{1}{0.5698} \right) \left( \frac{1}{0.9641} \right) = 0.3815 = 38.15 \text{ per cent.}$$

<sup>8</sup> A better way of estimating the current frictional minimum rate of unemployment is to use data for the entire postwar period rather than just the period between 1947 and 1957. Multiple linear regressions of  $U_L$  and  $U_{LL}$  on  $U_t$ ,  $U_{t-1}$ , and  $L_{45}$  for the 1947-63 period yield the following equations:

$$(5a) \quad U_L = -3.159 + 0.385U_t + 0.0441U_{t-1} + 0.0588L_{45}, \\ (0.730) \quad (0.0305) \quad (0.0304) \quad (0.0218)$$

where  $\bar{R}^2=0.948$  and  $\bar{S}=0.127$ ;

$$(8a) \quad U_{LL} = -2.157 + 0.175U_t + 0.0596U_{t-1} + 0.0414L_{45}, \\ (0.473) \quad (0.0197) \quad (0.0197) \quad (0.0141)$$

where  $\bar{R}^2=0.926$  and  $\bar{S}=0.0821$ . For  $\bar{L}=39$  per cent, these equations imply that very-long-term unemployment would disappear ( $U_{LL}=0$ ) if  $\bar{U}$  were stabilized at 2.3 per cent, and that all long-term unemployment would vanish ( $U_L=0$ ) if  $\bar{U}$  were stabilized at 2.0 per cent. Hence, at  $\bar{U}=2.0$  per cent all unemployment would be temporary and short-term, or frictional, unemployment.

where  $\bar{R}^2 = 0.947$  and  $\bar{S} = 0.0360$ , for the period 1947-57;

$$(10) \quad U_{LL} = 0.0767 + 0.459U_L, \\ (0.144) \quad (0.0834)$$

where  $\bar{R}^2 = 0.854$  and  $\bar{S} = 0.0644$ , for the period 1958-63. Thus, contrasting the later period with the earlier, not only is there a greater change in  $U_{LL}$  per unit change in  $U_L$  (0.46 vs. 0.44), but for any given value of  $U_L$ ,  $U_{LL}$  is greater than before (e.g., for  $U_L = 1$ , 0.54 vs. 0.42). In other words, not only have long-term unemployment rates increased relative to the over-all unemployment rate, but the duration of long-term unemployment has become longer.

These results would seem to permit one to draw the conclusion that the relative increase in long-duration unemployment has been due to an increase in structural unemployment and, because there has been a disproportionate increase in long-term unemployment rates, it must be so that structural changes have been, in whole or in part, the cause of the higher unemployment rates of the past six years.<sup>9</sup> But do they? What if it were possible to explain both the rise in  $U_L$  and  $U_{LL}$  relative to  $U$ , and the rise in  $U_{LL}$  relative to  $U_L$  without introducing the concept of structural change?

Imagine an economy with no technological change, no change in the composition of demand for either products or factors, and no change in the age-sex-color-geographic-educational-and-skill composition of its employed labor force. Assume that it is operating at the frictional minimum rate of unemployment,  $U_0$ . All unemployment is due to normal labor turnover and is short term. The flow into and out of this category is such that the probability of an unemployed worker finding a job within some specified period of time—say, 14 weeks—is one. Now suppose that the unemployment rate starts to fluctuate between  $U_0$  and  $U_1$ , rising to  $U_1$  during downswings in activity and falling to  $U_0$  during upswings. If the structure of wages (meaning, all hourly employment costs) conforms to the structure of skills, then decisions to lay off and rehire workers will be made on a random basis, provided there are no institutional rules that preclude such behavior. All workers displaced during

<sup>9</sup> This point of view has perhaps been most clearly stated by D. E. Diamond in [4, p. 35]:

In part, the higher unemployment was caused by the slowdown in the nation's economic growth. But structural changes are also responsible for some of the increase. Between 1957 and 1962 long-term unemployment (15 weeks and over) rose by 100 per cent and very long-term unemployment (six months and over) rose by almost 150 per cent. In the same period overall unemployment increased only 40 per cent.

Structural or technological unemployment differs materially from other major types of unemployment. Workers who are laid off due to seasonal or cyclical factors are usually back at work as the normal pace of business activity resumes. In contrast, the technologically displaced worker must seek a new position. He is likely to be unemployed for an extended period of time and may often be forced to take a job at substantially lower pay.

the downswings will get re-employed during the upswings, but the probability of re-employment within 14 weeks for any individual unemployed worker will be less than one. Although both the mean over-all and long-term unemployment rates rise, there is no chance of a "hard core" of unemployed workers developing because each unemployed worker is certain to have become re-employed by the time  $U_0$  is reached.

Imagine now that the unemployment rate rises from  $U_0$  past  $U_1$  to  $U_2$  and then falls only to  $U_1$ . Some of the workers displaced during the downswing in activity will remain unemployed during the succeeding upswing. The mean over-all and long-term unemployment rates increase; and if in subsequent cycles the unemployment rate simply fluctuates between  $U_1$  and  $U_2$ , the probability of an unemployed worker getting re-employed remains less than one. If the probability of re-employment within any specified period of time falls as  $U_t$  rises, then the ratio of both  $U_L$  and  $U_{LL}$  to  $U_t$  will be greater than it was when the unemployment rate merely fluctuated between  $U_0$  and  $U_1$ , and so also will be the ratio of  $U_{LL}$  to  $U_L$ .

A hard core of long-duration unemployed workers will emerge if the probability of re-employment is a decreasing function of the duration of unemployment. Among other reasons, this will be the case if the skill level of unemployed workers is also a decreasing function of the duration of unemployment, and if the structure of wages fails to adapt to the changing structure of skills; or if unemployed workers' skills remain intact but do not advance with the increasing level of skills of the employed labor force, and if the wage structure fails to adjust to the changing skill structure. Either way, the gap between the potential productivity of the unemployed and the actual productivity of the employed widens with time; and, therefore, the probability of re-employment diminishes with time. Under these conditions, the chance of a hard core of unemployed workers developing becomes the greater, the longer the unemployment rate fluctuates between  $U_1$  and  $U_2$ , for with each succeeding cycle the flow into the category of very-long-term unemployment exceeds the flow out of it. Hence, the ratio of  $U_{LL}$  to  $U_L$  will rise with time.

Under the assumed conditions, the hard core will be comprised of those whose skills have deteriorated the most, relative to those of employed or newly unemployed workers. The labor force components that would appear to be most vulnerable to skill decay through disuse are older workers and those with relatively low levels of educational attainment. These will tend to be overlapping sets if years of schooling completed and age are inversely correlated. When aggregate demand contracts and unemployment rises, these workers have just as much chance of becoming unemployed as any other labor force component,

provided that layoffs among workers of equal skill are made in a random fashion and not on a last-in, first-out basis. But when aggregate demand expands and unemployment falls, they have less chance of becoming re-employed than other workers, and their prospects diminish the longer they remain unemployed. An employer with one job vacancy and two unemployed workers from which to choose will not make a random selection, unless the choice is between workers of equal skill. Rather, he will tend to choose that worker whose skills have deteriorated the least through lack of use, unless he is constrained to do otherwise. Other things equal, this will tend to be the worker who has been unemployed the shorter time, and this in turn will tend to be the younger and more highly educated of the two.

Thus it is that persistent and long-term, or structural, unemployment—as distinct from temporary and short-term, or frictional, unemployment—can emerge in the first place (i.e.,  $U_L > 0$  and  $U_{LL} > 0$ ), can increase relative to all other unemployment (i.e.,  $\Delta U_L > \Delta U$ , and  $\Delta U_{LL} > \Delta U_L$ ), and can become increasingly concentrated among older workers (i.e.,  $\Delta U_L / \Delta U$  for older workers  $> \Delta U_L / \Delta U$  for all workers, and  $\Delta U_{LL} / \Delta U_L$  for older workers  $> \Delta U_{LL} / \Delta U_L$  for all workers) without there having occurred a structural change of any kind whatsoever. Therefore, from the mere fact that persistent and long-term, or structural, unemployment has increased, one cannot logically infer the presence of underlying structural change. In other words, a rise in structural employment can simply be the result of an increase in over-all unemployment and not in any way the cause of it. It is, therefore, no contradiction to say that inadequate aggregate demand can be the cause of a rise in over-all unemployment and that this in turn can generate a rise in structural unemployment.

### V. *Some Policy Implications*

If the preceding analysis of the problem is correct, it is clear that fiscal-monetary policy, unaccompanied by labor market policies which effectively restore the skills of the unemployed, cannot succeed in reducing unemployment to the neighborhood of  $U_0$  without simultaneously driving up the level of prices. But it is also clear that labor market policies, unless accompanied by a net increase in total expenditures, cannot reduce unemployment at all.<sup>10</sup> So, even if the problem of high unemployment is a pure case of a deficiency in aggregate demand (apart from those consistent with  $U_0$ , no job vacancies exist at all), both fiscal-monetary policy and labor market policy are required to reduce unemployment to  $U_0$  without inflation. Only if the problem is

<sup>10</sup> Labor market policies, however, tend to equalize the probability of re-employment among unemployed workers and thereby tend to reduce  $U_{LL}$  relative to  $U_L$ .

purely structural in nature (the number of job vacancies equals the number of unemployed persons), can labor market policy alone, and unaccompanied by a net increase in total expenditures, be relied upon to regain  $U_0$  without inflation. Except for this one limiting case, therefore, fiscal-monetary policy and labor market policy appear as essentially complementary policies and not as alternative means of obtaining simultaneously the goals of full employment ( $U = U_0$ ) and price stability.

It may occur to some that, since  $\bar{L}$  depends on the labor force participation rate of older workers, both  $U_L$  and  $U_{LL}$  can be reduced by any policy which reduces this participation rate—for instance, some kind of compulsory retirement program. This is indeed the case; but a decrease in the participation rate of older workers would also induce a decrease in over-all unemployment—directly, because some of those who retired would be unemployed workers; indirectly, because any withdrawal of employed workers from the labor force would open up job opportunities for those now unemployed. But it is clear from equations (5) and (8) that the resulting decreases in  $U_L$  and  $U_{LL}$  would be due principally to the reduction in  $\bar{U}$  and only incidentally to the reduction in  $\bar{L}$ . There is, however, a more fundamental consideration.

The existence of unemployment implies the presence of a gap between actual and potential output. This gap can be closed, and unemployment reduced, either by raising actual output to its potential or by lowering potential output to the actual. If the latter alternative were the only one possible, then a persuasive case could be made for policies aimed at reducing the fraction of older workers in the labor force. For example, if in 1960 all workers 45 years of age or older who were or became unemployed had been persuaded to retire from the labor force, then using the data contained in [16, pp. 195–203],  $L_{45}$  would have been 37.90 per cent (instead of 38.95 per cent); and  $U_t$  would have been 4.03 per cent, or 2.80 million persons (instead of 5.57 per cent, or 3.93 million persons). Hence,  $U_L$  would have been 0.86 per cent, or almost 600,000 persons (instead of 1.35 per cent, or 956,000 persons); and  $U_{LL}$  would have been 0.38 per cent, or about 260,000 persons (instead of 0.64 per cent, or 454,000 persons).<sup>11</sup> If the only alternatives facing these 1.13 million unemployed older workers were continued unemployment or compulsory retirement, it would have

<sup>11</sup> To take another example: If in 1960 all workers 70 years of age or older (about 1.45 million in number) had been persuaded to withdraw from the labor force (without regard to whether they were currently employed or unemployed), then  $L_{45}$  would have been 37.68 per cent;  $U_t$  would have been 3.58 per cent, or 2.48 million persons; and, according to equations (5) and (8),  $U_L$  would have been 0.72 per cent, or almost 500,000 persons, and  $U_{LL}$  would have been 0.36 per cent, or about 250,000 persons.

been difficult indeed for society to have resisted choosing the latter for it would have only involved the spurious sacrifice of giving up some nonattainable potential output.

But if it is also possible to reduce unemployment by increasing employment and thus to raise actual output to its potential—for instance, by an appropriate combination of fiscal-monetary and labor market policies—then choosing to reduce unemployment by imposing earlier retirement (or, for that matter, shorter work-weeks or work-years) on a portion of the labor force involves the real sacrifice of relinquishing some attainable potential output. Here, the case for earlier retirement and similar programs is less persuasive and clear cut, for the choice between them and policies directed at increasing employment depends on society's preferences between work and leisure, about which we (or, at least, I) know precious little. But in the absence of such knowledge, the prudent thing to do would seem to be to provide an economic environment which would permit people to make free and voluntary choices between work and leisure. In an economy whose rate of involuntary leisure has averaged 6 per cent for the past six years, this would mean the adoption of policies aimed not at sharing involuntary leisure among a larger group of people or institutionalizing it among a given group of people, but at eliminating it by simultaneously expanding the opportunities for gainful employment and adjusting the skill and geographic composition of the work force to the evolving pattern of labor demands.

Successful fiscal-monetary and labor market policies would reduce unemployment and permit workers voluntarily to substitute leisure for work by choosing shorter work-weeks, work-years, or work-lives. Actual output would be raised to its potential, but the level and rate of growth of potential output itself (productivity considerations aside) would depend upon the free choice of people between work and leisure. In contrast, successful participation rate (and related) policies would reduce unemployment and compel workers involuntarily to substitute leisure for work by requiring earlier retirement from, or later entry into, the labor force (or by requiring shorter work-weeks or work-years).<sup>12</sup> When viewed in this light, the proper course of public policy is clear.

## THE DEMAND FOR GENERAL ASSISTANCE PAYMENTS

By C. T. BREHM AND T. R. SAVING\*

. . . the growth of enlightened views as to the duties of the State and of private persons toward the poor, is tending to make it every day more true that those who have helped themselves and endeavoured to provide for their own future will be cared for by society better than the idle and the thoughtless. But the progress in this direction is still slow, and there remains much to be done yet. (Alfred Marshall, *Principles of Economics*, Bk. IV, Ch. 7, p. 226.)

The scope of relief which society gives to the poor has been a topic much discussed by economists. A major issue of these discussions is the extent to which relief payments, depending as they do on the idleness or near idleness of the recipients, will diminish incentives to seek or hold a job.

Pigou [7, p. 728] makes the following comment concerning relief payments:

. . . those [relief payments] which differentiate in favour of idleness and thriftlessness by making the help that is given larger, the smaller is the provision the recipients have made for themselves. Some resort to this type of transference is involved in all Poor Law systems that fix a state of minimum fortune below which they will not allow any citizen to fall. For, in so far as they raise to this level the real income of all citizens whose provision for themselves falls below it, they implicitly promise that any reduction in private provision shall be made good by an equivalent addition to State provision. It is plain that the expectation of these differential transferences will greatly weaken the motive of many poor persons to make provision for themselves.

Pigou continues with the following statement concerning the level of relief payments to the poor [7, pp. 731-32]:

But differentiation in favour of small provision made through temporary work is a serious matter. If, for example, it is understood that everybody's income will, at need, be brought up by State aid to, say, £3 a week, it will, generally and roughly, be to the interest of everybody capable of earning by work any sum less than £3 a week to be idle and earn nothing. This *must* damage the national dividend. How much it damages it will,

of course, depend on how large the sum fixed on as a minimum is, and how many people in the country would normally earn by work less than that sum. If the sum exceeds the normal earning power of a large part of the community, the damage done must necessarily be very great.<sup>1</sup>

In spite of this serious question, the level of welfare benefits relative to income levels tends to be dismissed as a factor influencing work incentives. Thus, in a report published by the U.S. Senate [10], the Advisory Council on Public Assistance urges a minimum standard of living without discussing the impact on work incentives. On the other hand, V. Carlson [3] and E. M. Burns [2] tend to emphasize the social status and psychological lift achieved through gainful employment, and Carlson [3, p. 200] seems to indicate that the relative level of public assistance to wages may have a short-run effect on work incentives. Burns [2, pp. 57-59], while asserting that the large majority of workers will always prefer work to relief payments, recognizes that there are "marginal groups of whom all this is not true."

These and other works suggest that there is a need for economic and statistical analysis concerning the effect of the magnitude of the public assistance payment on work incentives.

In Part I of this paper we present a theoretical exposition of those factors which might be expected to influence decisions to demand public assistance. Part II consists of a discussion of the data used in the estimation of the demand for public assistance. In Part III we present the estimation procedure, and Part IV contains a summary of our findings and policy implications.

### *I. A Theoretical Discussion of the Demand for Government Assistance Payments*

The demand for government assistance payments (hereafter referred to as G.A.P.) may be looked upon as a special case of the demand for leisure with the following qualifications:

1. If the consumer chooses to take G.A.P., he must specialize in leisure or, if he does work, he must earn below some minimum which society deems necessary for life.<sup>2</sup>
2. Society may place some stigma on the receipt of G.A.P. so that income from this source will be discounted by the recipient.

Consider an indifference map with real income ( $Y$ ) on the vertical axis and leisure ( $L$ ) on the horizontal axis (see Figure 1).

<sup>1</sup>In addition to this argument concerning the cost to society of the shift in the labor supply function due to the adverse effect of the existence of poor relief on work incentive, we have the effect on the incentives of the workers who must now be taxed to pay for the relief.

<sup>2</sup>If the G.A.P. recipient does work, his earnings are subtracted from his G.A.P.

Assume that the consumer's alternative to leisure yields wage rate ( $w_0$ ), the level of which is independent of the number of hours per day the consumer chooses to work, so that his income constraint consists of the line  $L^m Y^m$  in Figure 1. Given the indifference map represented by the solid indifference loci in Figure 1, the consumer will be in equilibrium at point  $A$  consuming ( $OL^0$ ) hours of leisure and receiving ( $OY^0$ ) income.

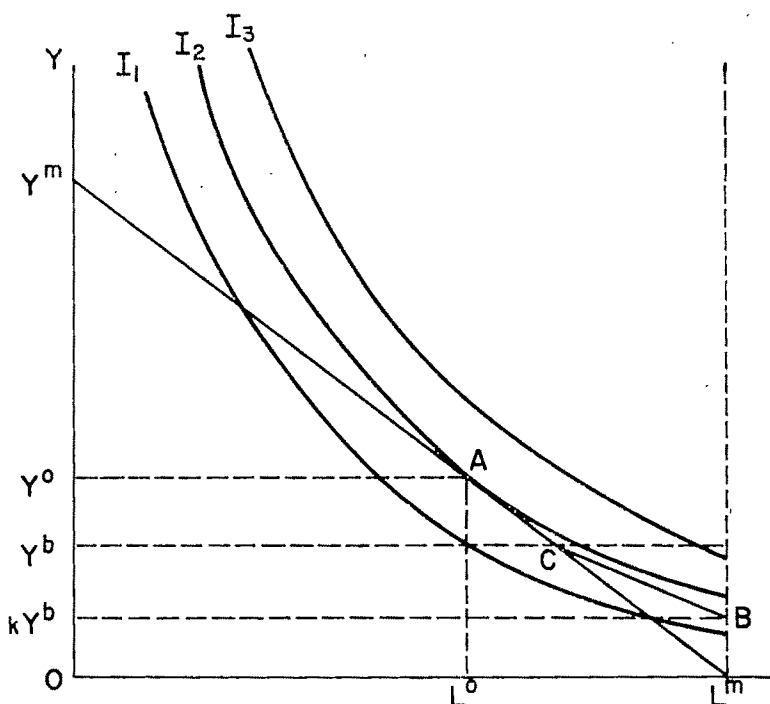

FIGURE 1

Now let us establish the level of income ( $Y^b$ ) which the state feels is the minimum necessary, "or proper," to sustain a consumer, i.e., for any consumer earning below this minimum the state will make up the difference between earned income ( $Y^e$ ) and the minimum ( $Y^b$ ), even if ( $Y^e$ ) equals zero. In addition, let us assume that some stigma is attached to the collection of G.A.P. so that the consumer applies to it a discount rate ( $k$ ), where  $0 \leq k \leq \infty$ . The discount rate ( $k$ ) would ordinarily be less than or equal to one but could exceed one for people who prefer living off the fat of the land. Given the existence of G.A.P. and the discount  $k$ , a new income constraint must be constructed. We begin at the point where the consumer specializes in leisure and re-

ceives the stigma-discounted G.A.P. income ( $kY^b$ ).<sup>3</sup> As the consumer begins to earn income, he views his income as his earned income plus ( $k$ ) times his portion of G.A.P., namely,  $Y^e + k(Y^b - Y^e)$ . Therefore the income constraint relevant for the decision of whether or not to demand a G.A.P. is given by the broken line  $L^mBCY^m$ .<sup>4</sup>

The institution of the G.A.P. program has resulted in the addition of the triangle  $L^mBC$  to the consumer's attainable set of combinations of income and leisure. Certainly such an increase in the attainable area cannot make the consumer worse off. Since the highest indifference locus the new income constraint is tangent to continues to be the original indifference curve  $I_2I_2$ , the consumer's equilibrium has not changed. However, a sufficiently large increase in the minimum income which society deems necessary or desirable (causing a parallel shift in line segment  $BC$ )<sup>5</sup> will result in the consumer's reducing his hours of work and demanding a G.A.P. income supplement.<sup>6</sup> Similarly, a decrease in the wage rate or an increase in the stigma-discount will increase the likelihood that the consumer will demand assistance payments.

If we now aggregate across consumers, we can get a demand schedule for assistance payments which, even though the individual demand

<sup>3</sup> If we assume nonsatiety of leisure, ( $kY^b$ ) will be the reservation income for the consumer. That is, the consumer's income, including any discounted G.A.P., must exceed ( $kY^b$ ) or he will specialize in leisure.

<sup>4</sup> The slope of line segment  $BC$  depends only on ( $w$ ) and ( $k$ ) and, hence,  $BC$  is linear. It can be proven easily since the consumer views his income constraint as:

$$(a) \quad Y = w(24 - L) + k[Y^b - w(24 - L)] \quad \text{if} \quad [Y^b - w(24 - L)] > 0$$

and

$$(b) \quad Y = w(24 - L) \quad \text{if} \quad [Y^b - w(24 - L)] < 0.$$

(a) above is the equation of the line segment  $BC$  and

$$\frac{\partial Y}{\partial L} = (k - 1)w. \quad \text{Q.E.D.}$$

<sup>5</sup> To show that line segment  $BC$  shifts parallelly due to shifts in ( $Y^b$ ), we need to show that the slope of the income constraint is invariant to changes in ( $Y^b$ ). Since

$$\frac{\partial Y}{\partial L} = (k - 1)w,$$

then

$$\frac{\partial \left( \frac{\partial Y}{\partial L} \right)}{\partial Y^b} = \frac{\partial^2 Y}{\partial L \partial Y^b} = 0. \quad \text{Q.E.D.}$$

<sup>6</sup> However, when Pigou [7, p. 731] states "it will, generally and roughly, be to the interest of everybody capable of earning by work any sum less than £3 a week [where £3 is our ( $Y^b$ )] to be idle and earn nothing," he must be assuming  $k = 1$ . For as we have seen, if  $k < 1$ , a consumer may choose (and a substantial number actually do) to work and collect a G.A.P. income supplement even though the consumer's total earnings are subtracted from his G.A.P.

functions are step functions, may be looked upon as the continuously differentiable function:

$$(1.1) \quad N = f(w, Y^b, k);^7$$

where  $N$  = number of assistance recipients,  $w$  = wage rate,  $Y^b$  = minimum income acceptable to the society, and  $k$  = average discount factor. The relevant partial derivatives have the following signs:

$$(1.2) \quad \frac{\partial f}{\partial w} < 0; \quad \frac{\partial f}{\partial Y^b} > 0; \quad \frac{\partial f}{\partial k} > 0.$$

The above discussion is based on the wage rate and the minimum level of income considered desirable by society, while, as seen in the introduction, those concerned about relief payments express themselves in terms of the absolute or relative incomes of relief recipients. However, it is a simple task to translate our argument, based on wage rates, into an argument based on earned income levels. For example, consider the indifference map depicted in Figure 1 and the initial equilibrium at point  $A$ . It is apparent that, given the equilibrium earned income ( $Y^o$ ), the higher the minimum income ( $Y^b$ ), the greater the likelihood that the consumer can make himself better off by demanding a G.A.P. Therefore, it appears that we may rewrite (1.1) above as follows:

$$(1.3) \quad N = h\left(\frac{Y^b}{Y}, k\right)$$

where:

$$(1.4) \quad \frac{\partial h}{\partial\left(\frac{Y^b}{Y}\right)} > 0; \quad \frac{\partial h}{\partial k} > 0.$$

In the following sections of this paper we bring the empirical evidence to bear on the question of whether the variables used in our theoretical analysis have their expected effect on the demand for G.A.P. In addition, we assess the empirical significance of these variables.

## II. *The Data*

Government assistance payments in the United States fall into two general types of programs. In the first group are programs operated jointly by the states and the federal government under the Social Security Act and its amendments. These programs provide for financial

<sup>7</sup>The individual either demands an assistance payment or does not. Hence, consider the step function:  $n_i = f_i(w, Y^b, k)$ , where  $n_i = 1$  if the  $i$ th consumer demands an assistance payment;  $n_i = 0$  if the  $i$ th consumer does not demand an assistance payment. If we aggregate across consumers with such demand functions, our dependent variable is  $n_i = N$ , which represents the number of assistance recipients.

aid to persons meeting specific qualifications which the recipient cannot meet through his own volition, either at all (age) or without taking quite drastic and often unlikely measures (blindness, total disability, dependent children) [12]. Since in these programs the deliberate choice of consumers between earned income and relief payments either is not present or is sufficiently inhibited that the effect would be small, we shall not consider them here. Similarly, the social insurance programs provide deferred earnings upon retirement or unemployment, and with respect to the latter, the period of coverage is limited and, hence, it cannot be treated as a permanent income alternative to work.<sup>8</sup>

A smaller group of programs called the "General Assistance Program" is available to those who do not meet the "objective" qualifications described above, but who still merit aid either because they are unemployable, i.e., have a zero wage alternative, or the level of income they are able to earn falls below the level deemed necessary or proper by society<sup>9</sup> [10, Appendix D]. These qualifications may be met by a deliberate action of the consumers and thus fall within the scope of our analysis. Consequently, we use data relating to this group of programs to test our analysis and to quantify the strength of the variables,

We therefore consider the number of general assistance recipients as the relevant dependent variable, i.e., as the ( $N$ ) in Part I of this paper. Data have been collected on numbers of G.A.P. recipients on an average per-month basis, annually by state for the period 1951-59 [13].

Unfortunately no direct measure of the average minimum level of income deemed desirable by society is available by state since the General Assistance Program is administered on a county basis rather than on a state basis. However, we do have data on the average G.A.P. income supplement by states on a comparable basis with the number of recipients. Therefore, we substitute the average monthly G.A.P. for the minimum income deemed desirable by society. We have collected these data by state annually for the period 1951-59 [13].

In addition to the above data, we have collected the following data on an average monthly basis, by state, annually for the period 1951-59: (a) average manufacturing wages, (b) population, (c) unemployment, and (d) nonagricultural employment [11]. We are using the average monthly manufacturing wage as the alternative cost of receiving a G.A.P., i.e., the wages which could have been earned if the

<sup>8</sup>This is not meant to imply that the demand for unemployment benefits is independent of the absolute level of the benefits or their level relative to wages, but only that they must be treated differently in the analysis. In addition, one generally must choose seasonal work in order regularly to demand unemployment benefits.

<sup>9</sup>In a few instances these payments are given where funds are needed to supplement the help given by the joint federal-state programs.

consumer chose a full-time job.<sup>10</sup> The rate of unemployment is necessary since it measures the number of consumers with zero wage alternatives. Unfortunately the general unemployment rate was unavailable by year by state, so we chose the insured unemployment rate. Non-agricultural employment, (d) above, when divided by population gives us a measure of the degree of urbanization by state.

Such a measure is useful for two reasons: (1) it has been suggested that the discount factor ( $k$ ) is smaller in rural communities than in urban communities, i.e., rural residents believe in the "Protestant Ethic" more strongly than do their urban counterparts; and (2) G.A.P. income supplements are not equally easy to obtain across the states and, as will be shown below, the degree of urbanization is closely and positively related to the ease of obtaining G.A.P. and, hence, is a good proxy for it. Thus, the greater the degree of urbanization, the greater will be the number of consumers demanding a G.A.P.

Lastly, we have classified the states according to the following three criteria: (1) allowance for an employed person in the household, (2) residence requirements, and (3) definition of "need" used in determining eligibility for a G.A.P. income supplement [14]. Each of these criteria represents in some sense the "ease" of getting on the G.A.P. rolls. Unfortunately, this classification could only be made for the terminal year of study.

### III. *The Estimation Procedure*

The data we have collected are a combination of cross-section and time-series, allowing us to take account of the effect of migration of consumers from the states in which G.A.P. payments are low to states where G.A.P. payments are high. If, as one would expect, such an adjustment will require several years, we can expect the disturbance terms for a given state in a given year to be positively correlated with the disturbance terms for that state in the closely preceding and succeeding years. This relationship between the disturbance terms allows us to increase the efficiency of our estimates by utilizing Aitken's generalized least squares [1]. Zellner has developed a technique for using the Aitken generalized estimators when the disturbance variances and covariances are unknown [8]. This method allows us to make use

<sup>10</sup> We would prefer the average wage rate available to the G.A.P. recipient. However, this would require knowledge of the distribution of G.A.P. recipients by skill by state and the wage rates by skill by state. Since these data are not available to us, we chose average monthly manufacturing wages as the best available alternative. In addition, if the distribution of general assistance recipients by skill is different from the skill distribution embodied in the average manufacturing wage, this measure is erroneous. However, as long as the difference in skill distribution does not differ systematically, no bias will result.

of both the cross-section and the time-series aspects of our data.

Unfortunately, as we noted in the preceding section, the classification of the states by the ease of getting on the G.A.P. rolls was only available for the terminal year of the data. Therefore, we are faced with the following choices for the handling of this variable: (1) disregarding what is certainly a significant determinant of the number of G.A.P. recipients, (2) assuming that the classification for the terminal year is valid throughout the period, or (3) finding a proxy variable for this classification which is available for the entire period.

Fortunately some work has already been done which indicates that the ease of getting on the G.A.P. rolls should be positively related to the degree of urbanization of the state.<sup>11</sup> In order to test this hypothesis we regressed our measure of degree of urbanization ( $NA^*$ ) for the terminal year (1959) on the three classification variables representing the ease of getting on the G.A.P. rolls with the following results:

$$(3.1) \quad NA_i^* = 30.62 - 0.75E_i - 3.58R_i - 1.50M_i; \quad \bar{R}^2 = 0.314; \quad m = 48;$$

(0.85) (0.74) (1.18) (0.70)

where

$NA_i^*$  = nonagricultural employment as a percentage of the population in the  $i$ th state;

$E_i$  = a dummy variable taking the following value:

0—if the  $i$ th state allows G.A.P. recipients to be employed;

1—if the  $i$ th state sometimes allows G.A.P. recipients to be employed;

2—if the  $i$ th state never allows G.A.P. recipients to be employed.

$R_i$  = a dummy variable taking the following value:

0—if the  $i$ th state has no residence requirement;

1—if the  $i$ th state has a residence requirement but allows exceptions;

2—if the  $i$ th state has a residence requirement and allows no exceptions.

$M_i$  = a dummy variable taking the following value:

0—if the  $i$ th state responds to any "kind" of a need of an eligible family or individual;

1—if the  $i$ th state responds to only specified types of need;

2—if the  $i$ th state responds to only "emergency" needs.

<sup>11</sup> This hypothesis is a combination of two studies. The first, by J. Heffernan, indicates that if the population is ranked on a liberal-conservative scale, those on the liberal end of the scale are more favorable to public assistance [4]. The second study by V. O. Key indicates that the more urbanized areas are more likely to fall on the liberal end of the scale [5]. Therefore, the more urbanized areas are likely to be more favorable to the G.A.P. program and to make the eligibility requirements easier to meet.

Equation (3.1) clearly indicates that the degree of urbanization as measured by the percentages of a state's population employed in non-agricultural pursuits is indeed a good proxy for the ease of getting on the G.A.P. rolls. All the coefficients of the dummy variables had the expected sign, and two of the three were significant at better than the 1 per cent level.

On the strength of equation (3.1) we have chosen the proportion of nonagricultural employment to population in each state as the proxy variable for ease of getting on the G.A.P. rolls. In addition, we assume that the distribution of income and ability within each state is constant for the period under consideration, so that we may express the number of assistance recipients in a given state as a percentage of that state's

#### IV. *The Empirical Evidence*

##### *A. The Results of the Estimation*

The generalized least-squares results of the equation sets described in the previous section are given in Table 1. Inspection of Table 1 indicates that every equation contains at least one coefficient which is significant at better than the 1 per cent level, and in 26 of the 36 equations estimated there were at least two significant coefficients (at the 10 per cent level). Thus, our model is able to explain significantly the observed variation in G.A.P. recipients.<sup>12</sup>

In Table 2 we have summarized the results in Table 1 by presenting cumulative frequencies of coefficients significant at the 1, 5, and 10 per cent levels by equation set and coefficient.<sup>13</sup>

Inspection of Table 2 reveals that the G.A.P. income variable was consistently the most significant variable and had the correct sign in all cases. This is true whether this variable appeared in absolute terms, ( $P$ ) in equation sets (3.23) and (3.24), when it was significant in 16 of 18 cases at the 1 per cent level and in all 18 cases at the 10 per cent level, or in relative terms, ( $P/W$ ) in equation sets (3.21) and (3.22), when it was significant in 17 of 18 cases at the 1 per cent level.

The coefficient of the rate of unemployment ( $U$ ) was significant in three of 18 cases at the 1 per cent level and seven of 18 cases at the 10 per cent level in equation sets (3.21) and (3.22), while this coefficient was significant in seven of 18 cases at the 1 per cent level and in 15 of 18 cases at the 10 per cent level in equation sets (3.23) and

<sup>12</sup> Since the estimating technique used does not minimize the squared deviations around each individual regression, the multiple  $R^2$  is not a relevant statistic.

<sup>13</sup> The standard errors on which the significance levels are based are asymptotic standard errors. However, Zellner [9] has indicated that for the model which he investigated the finite sample results are not very different from the infinite sample results whenever  $n \geq 20$ . (In our case  $n = 48$ .)

<sup>b</sup> This coefficient does not have the expected sign.

(3.24). Moreover, the coefficient of unemployment had the correct sign in all but three cases, and in each of these the standard error exceeded the coefficient.

The coefficient of our proxy variable for the ease of getting on the G.A.P. rolls had the expected sign in 17 of 18 cases where it appeared, and in the one case of wrong sign the standard error considerably exceeded the value of the coefficient. In addition this variable was significant in four of the 18 cases at the 1 per cent level and in nine of the 18 cases at the 10 per cent level.

In equation sets (3.23) and (3.24) the coefficient of average manufacturing wages (*W*) is significant in only two of 18 cases, once in each equation set associated with the absolute wage level, and has a positive rather than the expected negative sign. This coefficient does have a negative sign, albeit insignificant, in only four of 18 cases. However, considering that in 10 of 14 cases where the coefficient is positive, the standard error exceeds the coefficient, while in three of four negative cases the coefficient exceeds the standard error, it is very likely that our results are simply due to chance.

In addition, it can be argued that interstate differences in average manufacturing wages reflect to a large extent differences in skill and educational distributions of the population and, hence, do not reflect differences in the alternative cost of receiving G.A.P.<sup>14</sup> In view of this problem we have re-estimated equation sets (3.23) and (3.24), excluding average manufacturing wages, and we present the results of this estimation in Table 3.

<sup>14</sup> If, as is sometimes asserted, wages by occupation do not differ by state, then the wage variable is irrelevant in a cross-section analysis.

The results of equation sets (3.23\*) and (3.24\*) presented in Table 3 indicate that the G.A.P. income variable is again the most significant of all variables included, being significant in 17 of 18 cases at the 1 per cent level and in all 18 cases at the 10 per cent level. The sign was as expected in all cases. The coefficient of unemployment was significant at the 1 per cent level in five of 18 cases and at the 10 per cent level in 13 of 18 cases. This variable had the wrong sign in only one of 18 cases, and in this case the standard error exceeded the coefficient by over four times.

Our proxy variable for ease of getting on the G.A.P. rolls had the expected sign in all cases and was significant at the 1 per cent level in two of nine cases and at the 10 per cent level in three of nine cases.

### *B. The Interpretation of the Results*

The results discussed in the above section clearly indicate that the level of G.A.P. income is an important variable in explaining the percentage of a state's population which is on the G.A.P. rolls. The unemployment rate results indicate that while the variance in consumers with zero wage alternatives does explain a significant portion of the variance in G.A.P. recipients, it is an inferior explanatory variable to the G.A.P. income variables. In addition, our proxy variable for the ease of qualifying for the G.A.P. rolls presents further evidence for the conclusion that consumers react to the costs and returns of the G.A.P. program in determining whether or not to demand a G.A.P. income.

However, we must point out that such a relationship between G.A.P. income and numbers of G.A.P. demanders does not imply that society should not give G.A.P. income supplements. Consumers may have the "best" of reasons for choosing a G.A.P. income rather than working, e.g., the case of a widowed mother of several children. In this case there is a cost to society of such a person's working, and hence we institute a program which, while it does not force all widowed mothers to stop working, makes it more likely that they will come to this decision. The fact that some consumers may take steps to qualify for the program does increase the marginal social cost of the program, but does not imply that at the current levels the marginal social costs exceed the marginal social benefits.

In addition to these problems of interpretation of the results, we might wonder if possibly the use of the dummy variables themselves rather than the proxy we used might have affected the results in some way. In particular, if the level of the G.A.P. incomes is related to the ease of getting on the rolls and this ease is not clearly reflected in our proxy variable, part of the significance of the G.A.P. income variables may be due to this omission.

To test this hypothesis we ran single-equation least squares on the terminal years data of equation sets (3.22) and (3.24\*), and then ran these same data, replacing the proxy variable ( $NA^*$ ) with the dummy variable used in the previous section. The estimates of the coefficients of the G.A.P. income variables and unemployment are given in Table 4.

Inspection of Table 4 shows that, contrary to the above hypothesis, the substitution of the dummy variables for our proxy increases both the level of the coefficients of the G.A.P. income variables and their

significance. This at least indicates that our results are not due to the exclusion of the ease of getting on the G.A.P. rolls as measured by our dummy variables. However, the actual enforcement of the rules we have used may differ systematically by state and be positively related to our G.A.P. income variables. However, this is simply a conjecture, and no data are available to test it.

If we are willing to make a few heroic assumptions, we may get some further evidence concerning the effect of the level of G.A.P. income on the demand for assistance. Let us assume that the constant term represents the "hard core" of unemployables. We can then ask the following question: What would be the average percentage of the population receiving G.A.P. in the various states if unemployment were zero and there were no "hard core" of unemployables. In other words, we take equation sets (3.21) and (3.23\*), assuming that the unemployment is zero, and compute expected levels of percentage receiving assistance payments. From these expected levels we subtract the "hard core" of unemployables, i.e., the constant term, wherever it is positive. We then divide the remainder by the average of the percentages of the various states' populations receiving assistance. Thus, we get an estimate of the percentage of general assistance recipients due to the level of the assistance payment rather than zero wage alternatives. These percentages are presented in Table 5.

Table 5 shows that the percentage of assistance recipients due to the level of assistance payments ranges from 22.9 to 87.3. Considering the standard errors of the original estimates from which these were

TABLE 5—THE PERCENTAGE OF GENERAL ASSISTANCE RECIPIENTS DUE TO THE LEVEL OF ASSISTANCE PAYMENTS

derived we cannot place a great deal of faith on any one year's estimate. However, the two means may be considered with a great deal more confidence, and both of these indicate that nearly one-half of all assistance recipients are not on assistance due to zero wage alternatives.

It is important to remember that the validity of the above method depends on several conditions: (1) that the underlying relationship is in fact linear even for large changes in the explanatory variables; (2) that the variables themselves measure what we claim they measure. We trust that the latter condition holds, but we make no pretensions that the former does.

### V. *Summary and Conclusion*

On the theoretical level we have shown that the demand for G.A.P. can be treated as a special case of the traditional theoretical treatment of the demand for leisure. In this treatment we conclude that the decision of whether or not to demand a G.A.P. depends on: (1) the consumer's earned income; (2) the minimum income which society deems desirable; and (3) the discount factor which the consumer applies to relief doles. The analysis suggests that in addition to the "hard core" of unemployables and low-income earners the set of G.A.P. recipients should contain consumers who deliberately have chosen to bring their earned income below the minimum set by the society.

On the empirical level the analysis reveals the following results:

1. The G.A.P. income variables are positively related to numbers of assistance recipients, and in addition these variables are more significant than any other used in the analysis.

2. While the variance in the number of consumers with zero wage alternatives, as measured by the rate of insured unemployment, was positively related to numbers of assistance recipients, it was not as

significant a factor in explaining the variance in these assistance recipients as the G.A.P. income variables.

3. The ease of meeting the qualifications to get on the G.A.P. rolls, as measured by a proxy variable indicating degree of urbanization, is positively related to numbers of recipients and reinforces the conclusion in (1), since this represents a cost factor in the G.A.P. program.

In conclusion, we reiterate the fact that the results contained do not imply that the G.A.P. program should be stopped or cut back, but only indicate that G.A.P. recipients are like the remainder of consumers in that they react to economic incentives.

## Notes on Marxian Economics in the United States<sup>1</sup>

*Cuius regio eius religio*

### I

Paul Baran's premature death March 26, 1964, deprived U.S. economics of its last eminent academic practitioner professing Marxism in both theory and policy. Considering the importance of Marxian economics in the current world, and likewise the U.S. tradition of liberalism, questions arise. What really goes on here? How much more freely do the hundred flowers really bloom, and the hundred schools of thought contend, in Jefferson's America than in Mao's China?

The vacuum created by Baran's death may conceivably be only temporary. This writer knows of only marginally orthodox resident candidates for the succession, but more promising prospects may exist. There is also a wide world from which to draw, including not only foreigners like Baran himself but also U.S. refugees from Joe McCarthy and successors. It is also true that Socialists of whatever variety have never thrived in U.S. departments of economics.<sup>2</sup> With the Cold War, however, the tiny minority of Marxists in particular has shrunk with peculiar sharpness, considering the over-all expansion in the numbers of university economists. Vacancies created by this expansion, or by deaths and retirements, go to less controversial figures. Baran's own place at Stanford will probably share the general fate. Questions about the hundred flowers and schools of thought remain decidedly—some say ominously—in point.

It is no part of my intention to memorialize Baran himself. This is a task for others who knew him better than I did. Yet I cannot avoid two features of his career. (1) As a Soviet citizen, Baran had sufficient courage to maintain Bukharinist deviations during Stalin's heyday, belying the stereotype of the Communist scholar degenerating to a Party mouthpiece. (2) By reason less of rhetorical and analytical competence than of resistance first to Stalinism and then to embryonic U.S. Fascism, Baran's international reputation and that of his writings—notably *The Political Economy of Growth* [1]—outrun their domestic fame. This is what makes the maintenance of Baran's dissident tradition more important, particularly to the international stature of U.S. economics, than academic deans or chairmen realize, with minds preoccupied by trustees, regents, or legislators.

<sup>1</sup>Parts of this essay draw upon a public lecture on "Academic Freedom Problems in American Economics," given at Kobe, Japan, in January, 1964. The writer is grateful to Dean Hiroshi Shinjo of Kobe University for criticisms of the original lecture.

<sup>2</sup>There is substantial historical literature on the spotty U.S. record in academic freedom issues involving economic matters, concentrating on the half-century prior to World War II. Two citations may suffice: Richard Hofstadter and Walter P. Metzger [4, Ch. 9] and Harold Laski [5, pp. 355-60, 368 f., 381-92].

## II

Why has Marxian economics always been so weak in our economics departments, and why has it declined since the end of World War II? There are two obvious explanations, one complacent and the other alarmist; the truth lies somewhere between the two.

The complacent explanation is of course that Marxian economics, like Physiocracy, *Historismus*, and Social Darwinism, has lost out in free and fair competition on "the market place of ideas" of the Affluent Society. Where it survives, it is only a secular religion, imposed by rote in totalitarian regimes or by totalitarian political parties. The alarmist explanation is that Marxism in general, including Marxian economics, is persecuted systematically by the U.S. power elite; its weakness proves both the anemic character of U.S. academic freedom and the imminence of Star-Spangled Fascism.

There are at least two dubious features in the complacent or competitive explanation. One is the somewhat unusual outcome of ideological competition in the United States, as compared to other countries of the anti-Communist world. The other is the institutional working of the U.S. systems of graduate training for economists and achievement of academic tenure, as they affect the prospective economics teacher with Marxian leanings.

To say that Marxian economics is weak in the United States involves comparison not only with the Communist blocs, but with almost any country one cares to name (excluding the Iberian peninsula, South Africa, Antarctica, and similar Rightist or illiterate enclaves). Most other countries foster Marxian economists of varying popularity, influence, competence, and sophistication. In many places, the Soviet textbook, *Political Economy* [11] (not a prepossessing standard-bearer), has outsold Marshall and Samuelson combined, with the aid of some loss-leader pricing. On many, if not most, Japanese campuses, for example, the most popular U.S. economists are Paul Sweezy and Paul Baran, and the Labor Research Associates' analyses of the U.S. scene take precedence over anything the Council of Economic Advisers or the National Bureau can offer.

This is not to suggest that "they" are right while "we" are wrong. Ideological competition in academic market-places overseas is marred by prejudices operating in an anti-American, and therefore anticapitalist, direction. Foreign intellectuals, economists included, are simultaneously jealous of our (relatively) high pay and comfortable working conditions; they are contemptuous of the ambiguous position of the "egghead" in our business society, and exaggerate our resistant racisms. We can see the moles in their eyes, but may there not also be beams in our own—meaning in this context, imperfections in U.S. ideological competition?

Here let us overlook the ownership and control of mass communications, to consider only the U.S. systems of graduate training for economists and the limitations on academic freedom and tenure in this country. Certain features that we feel necessary to maintain reasonable standards of competence seem positively menacing from the viewpoint of a foreign Marxist. Without accepting Seligman's [9] dismissal of contemporary orthodoxy

as technique for its own sake, one can admit that, in raising the mathematical and statistical standards of U.S. economics, we have probably displaced something. What has that "something" been? It varies, no doubt, from one institution to another, but basically it is a melange of foreign languages, economic and intellectual history, philosophy, law, allied social studies, and/or (more usually and) concern with unconventional and "obsolete" positions within economics itself. The neophyte with simultaneous leanings to both academic economics and analytical Marxism faces, at the outset of graduate training in the former, some four to six years in which the latter interest pays off, if at all, only by assimilation in particular planning and programming techniques (input-output and its applications). If the "Economics of 1984" leaves him cold, he has nowhere to go but abroad, nothing to do at home but convert to some variant of more conventional wisdom, or abandon theoretical economics altogether.

Passing from training to tenure problems, the most "natural" approach, internationally speaking, probably resembles the Austro-German *Katheder* system more closely than the U.S. one. A typical *Katheder* consists of an Ordinary (Full) Professor, an Extraordinary (Associate) Professor, an Instructor, and one or two Assistants. (There are also *Privat-Dozenten*, licensed teachers marginal to the system, whom we ignore.)<sup>3</sup> Once the aspirant is under the aegis of the *Katheder*, even as a lowly Assistant, some modest future is secure for him. He may never rise, and may live out his career as a perpetual malcontent. However, Fascism and revolution aside, he has tenure, his salary escalates with his years of service and family responsibilities, and he ends his days on a modest pension. He can live the life of "ein Mann, der anders denkt," as controversially (or conventionally) as he pleases. In the United States a similarly limited and stuffy approach to Nirvana normally requires at least seven years in the limbo of short-term contracts, and/or promotion to associate professor. In terms of years and hostages to fortune, the representative U.S. economist withdraws his spouse from the "Ph.T." labor market, and brings one or more children into the world, before passing under the tenure umbrella. This is no "fate worse than death" in a growing economy with teacher shortages—unless, of course, our aspirant becomes *persona non grata* to the hiring authorities! This he may do in a number of ways, none surer than premature labeling as a controversial figure. To put it bluntly, the aspiring Marxist with academic ambitions had better hold his Marxism in cold storage for five or ten years until he has tenure at a good school and his youthful fervor is diluted with fuddy-duddyism, alias maturity. Small wonder if, as an economist, he avoids the academic calling, or if, as an academician, he selects some less "sensitive" department!

Mary McCarthy's *Groves of Academe* [6] features an obnoxious English teacher who wins tenure from a self-consciously liberal college president by

<sup>3</sup>To ignore the *Privat-Dozenten* is admittedly to overrate the liberalism of the Austro-German tenure system, since many a dissident, including Karl Marx as an aspiring philosopher, was left to wither on this vine. The *Privat-Dozent* had tenure—in an economically meaningless form. He was licensed to teach, but received no salary. His income came from the fees of whatever students cared to study under his direction.

inventing a Marxist background, complete with fictitious Communist Party membership, and daring the president to let him go. Whatever happens in English at "Jocelyn College," economics in flesh-and-blood institutions is rather different. The most famous case in point is that of Paul Sweezy, already mentioned as one of America's most influential economists among "progressive intellectuals" overseas. Sweezy did not achieve tenure at Harvard, shortly after the publication of his *Theory of Capitalist Development* [10]. Under the Harvard "up or out" system he would presumably have been asked to resign, unless another vacancy opened up within his ken. In fact, he resigned well before the deadline to accept a temporary government position. Thus far, the Sweezy story is no different from dozens of others. There is little if any evidence connecting his Marxism with the (extraordinarily close) Harvard decision against his promotion to tenure rank. Only the sequel sets his case apart. Other losers in "the Harvard competition" are recommended for, and achieve, tenure positions at good universities. Sweezy, on the other hand, was supported for no desirable academic assignments whatever, and achieved none. Thanks to private means, he was able to co-found the Socialist journal *Monthly Review*, and later the associated Monthly Review Press. Twenty years after, there are Marxists who insist that Sweezy was purged for his beliefs, first from Harvard and then from academic life. The charge is palpably false as regards Harvard, but not as regards the academic community, where "we have no academic freedom problems; we are careful whom we hire."

Given the imperfections in our ideological competition, it is not difficult to rationalize them under the rubric of "maintaining standards." In terms of contemporary jargon about multiple goals and trade-offs between them, my own rationalization (to foreign questioners) is rather crude. Four of the professional goals, conscious or otherwise, of academic economists are (1) high real incomes, including such psychic elements as social prestige and comfortable working conditions; (2) low responsibilities of what medical men would call the "scut-work" of the profession, namely the teaching and administration of unpromising and disinterested "warm bodies," alias students, from freshmen on up; (3) freedom to set our own professional standards and choose our own colleagues; and finally (4) freedom to expound and publish what we believe correct and expedient—academic freedom in the conventional sense. For the sake of the first three goals, we permit some erosion of the fourth, not for ourselves but for our junior, pre-tenure colleagues. We may have chosen consciously or viscerally, wisely or foolishly, but we have chosen. So—consciously or viscerally, wisely or foolishly—have our foreign (and some domestic) critics. Whether the U.S. choice involves important elements of "selling out" or becoming "kept cats," God alone can determine, but many can suspect. Either choice, ours or theirs, can be honestly wrong or, for that matter, dishonestly right. If the U.S. choice be wrong, it is within our power to modify it in the direction of foreign practice to a greater extent than foreigners are free to move in the direction of the U.S. system.

Which is in fact the correct choice? With the "subjectivist bias" of "bourgeois decadence," I am quite unable to say. I personally favor some revision

of the trade-offs between our goals in the direction of what one observes abroad, but only to refurbish the international repute of U.S. liberalism here and now, not for the sake of abstract virtue or the correct line *sub specie aeternitatis*.

### III

If the low standing of U.S. economic Marxism cannot be explained exclusively by perfect competition between ideas, the rival explanation—persecution and discrimination—is likewise incomplete. A number of its difficulties are fairly obvious.

In the first place, if U.S. Marxism is weak in any pure or self-assertive form, it is also strong as a pervasive element in an eclectic whole. (The mutual consistency of the Marxist and "bourgeois" parts of this eclectic whole may be questionable, as characteristically happens with eclectic doctrines.) We might say that U.S. academic economics is simultaneously full of Marxism and empty of Marxists!

The "eclectic whole" of the last paragraph is left-wing Keynesianism of the liberal-labor, or "lib-lab" variety. Its strongest proponent is perhaps the late-model Joan Robinson. In the United States the name of Leon Keyserling, a nonacademician, comes to mind. Academic left-wing Keynesianism is pro-government, pro-planning, pro-labor, pro-redistribution, anti-business, anti-free market, and antimilitary. It is, in advanced countries at least, more Social Democratic than Leninist. It is reformist rather than revolutionary in politics, parliamentary rather than conspiratorial. It is, as we have suggested, eclectic in its intellectual borrowings. Keynesians are not only at least as Keynesian as they are Marxist, but also as Veblenian, or sometimes even Marshallian. (The orthodox Marxist, by contrast, hates to borrow outside the fold. If religious analogy is permissible, the U.S. lib-lab is Unitarian where the Marxian is Fundamentalist.) On specific public policy questions, however, lib-lab and Marxian views have run parallel with sufficient frequency to disturb William Buckley [3],<sup>4</sup> Merrill Root [8], and the *National Republic*. Whether the lib-lab or the New Frontiersman "dominates" our academic economics is a complex, if not a meaningless, question and permits no uniform or easy answer, but can we not agree that, dominant or not, this eclectic Keynesian Left, Marxian overtones included, has suffered no widespread or effective persecution?

Even turning from lib-labs to forthright Marxists, the domestic, resident campus economist is far from the whole story. Marxists work in unions, research organizations, journalism, the Civil Service—perhaps even Madison Avenue—in larger proportions than in universities. On college campuses, the Marxian economist, often self-trained, is found more frequently pursuing some other interest in some less sensitive department. A few outsiders, including Sweezy, not only lecture at leading universities but hold temporary appointments for a term or a year at a time. An occasional economics department compromises with suspicious trustees or legislators and presents the Marxian

<sup>4</sup>Incidentally, none of the Yale economists attacked by Buckley was a Marxist, although several might have been called "lib-labs."

position to graduate students through a series of visitors from various European and Asian countries, including Iron Curtain borderlands like Poland and Yugoslavia. These visitors' offerings are too scattered and irregular to make up an organized program in Marxian economics through Marxian eyes, but they help Socialist students devise such programs independently of the permanent faculty.

We should also mention the various Marxian "seminars" or "study groups" which meet openly, if sporadically, on many famous campuses. These informal groups, always including and sometimes stressing the economic side, are conducted by faculty members of "other" departments (from the humanities to the natural sciences), by off-campus Marxists, or by advanced students, usually from countries whose curricula have stressed Marxist points of view.

How seriously these groups are taken, and what level of sophistication they attain, is hard to guess. The thrill of forbidden fruit seldom outweighs for a long period the lack of academic credit—especially where the fruit is not really forbidden! Yet there have been exceptions to this generalization, as at Harvard in the 1930's and Berkeley in 1947-52. Conservative economists have sometimes complained about students slighting sound economics in favor of seditious seminars and occasionally have tried to drive off-campus such unfair competition to their mummified lecture notes. What is more important to the present discussion is that the seminars run openly, and that the professors or graduate students who organize and conduct them are seldom discriminated against in any significant way, unless the seminar's "unity of theory and practice" develops into riotous demonstrations or recruiting for the Spanish Civil War. Rather than being suppressed, Marxian seminars and study groups are generally tolerated as buffers between timid administrations and impetuous students, and as providing the latter a chance to "let off steam."

Nature abhors a vacuum, and if there existed any crypto-Fascist conspiracy to suppress Marxian economic thought in the United States, it would logically include replacement of even Left Keynesianism with some more conservative brand of revealed truth. Such campaigns do in fact exist, but remain toothless and anemic, except at the kept colleges of particular business groups or religious sects. (Harding College in Arkansas and Grove City College in Pennsylvania are prototypes of this sort of institution.) Beyond these vest-pocket academies, the conservative anti-Keynesian campaign takes such unexceptionable forms as distributing in cheap editions the works of Austrian School and Social Darwinian writers, providing summer employment for college teachers within the management cadres of Big Business, and sponsoring seminars where invited speakers propound conservative doctrine.

What has this campaign accomplished to date? A *Gedankenexperiment* may be in point: Suppose that a college or university had the choice of inviting as visiting professor for a year, at no cost to itself, either an outstanding off-campus Marxian economist like Victor Perlo or an eminent off-campus conservative economist like Henry Hazlitt. Which would its economists prefer? My forecast would be that, Hardings and Grove Cities aside, a full two-

thirds would select Perlo. If so, the conservative counteroffensive has thus far been a failure.

Anticonservative feeling among university economists sometimes extends even further, to cover fellow-academicians as well as eminent outsiders. On at least a substantial minority of U.S. campuses, such academic eminences as Milton Friedman and Armen Alchian are more often sponsored primarily by student Conservative, Individualist, or Republican Clubs than by economics departments proper. At the same time that they are suspected of suppressing campus Marxism and Marxian economics, conservatives complain of their own exclusion from contact with economics students, at least outside of business schools. One conservative writer, Ayn Rand, has, on grounds of its altruist and collectivist bias, given up hope for the present generation of intellectuals, economists included, and called for replacement by an entirely new group, trained largely outside the present hierarchy and uncontaminated by it [7, pp. 10-57].

#### IV

So the marginal status of Marxism in U.S. economics proves little if anything. It proves neither the inferiority of Marxism in free ideological competition, nor yet the falsity of U.S. claims to academic freedom. Elements of both explanations are initially plausible, but neither case is correct to the point of excluding the other, as a hypothesis if not a fact.

In such a muddled and muddy situation as this, it is almost inevitable to end, like T. S. Eliot's world and *Wasteland*, "not with a bang but a whimper." The writer's particular whimper or whimpers are intended to decrease the imperfections of our market place of ideas, in their relation at least to the Marxian heresies.

The first whimper: As U.S. Marxists are currently required to study, to the point of considerable technical familiarity and some risk of conversion, contemporary marginalist price analysis and income and employment theory, we might well require of all aspiring economic theorists a considerable degree of familiarity with some important dissident positions, including the Marxian one. There is no longer any excuse for repeating as *Marx-Kritik* all the miscomprehensions of Böhm-Bawerk's famous review of the 1890's [2], which treats Marxism exclusively as static price theory, and gives it failing grades.

The second whimper: More U.S. universities, particularly those which foreign students attend in large numbers, should follow the Stanford practice when Baran was hired shortly after World War II. They should bend over backwards to include competent Marxists in their economics faculties, as tokens of the viability of the U.S. liberal tradition and in contrast to the situation prevailing in Mainland China or the Soviet Union. At first, perhaps, trouble would be minimized if the men selected were neither closed-mind Party fanatics nor particularly charismatic types, and if they were kept out of the "thundering-herd" lecture sections of the principal undergraduate courses. Eventually, if all goes well, even these barriers might be lowered for Marxists to the same extent as for others.

Some such tendencies may develop automatically, if the teacher shortage

continues. The ban on the linguistically handicapped teacher, never severe in the United States, has almost vanished, especially where mathematics is a workable substitute for English. The bans against minority races and religions, and against neurotics, "deviants," and females are falling and failing too. Rather than conclusive "three-strike" handicaps, they are down to the "one-strike" level in most institutions. Defensible prejudices against the intellectually handicapped are yielding likewise. What was unpardonable stupidity and incompetence in depressed periods is now called "practical," "realistic," and even "good undergraduate teaching." In this environment, is it too much to anticipate some similar improvements for the ideologically handicapped? As for Marxists like Baran: In the first place, they may be more right than the rest of us. In the second place, even if they are not, might not lowering their handicap from three strikes to one pay for itself in refurbishing our overseas image? Or would it be too little and too late?

#### The Neoclassical Theorem

The object of this paper is to present a diagrammatic proof of the neoclassical theorem that, in balanced growth, consumption per man is maximized when the marginal product of capital is equal to the natural rate of growth.<sup>1</sup>

<sup>1</sup>We are assuming a one-commodity world so that no index-number problem arises in defining the marginal product of the capital. The incremental output of consumer goods is of the same stuff as the stock of capital, and the marginal product of capital is a pure number with the dimensions of the rate of interest.

Our proof has a number of advantages. Firstly, it makes use of the production function and so focuses on the purely technological nature of the theorem. Secondly, it is perfectly general since it can incorporate both the rate of population growth and Harrodian neutral innovations. Thirdly, it facilitates the ease with which the theorem is grasped since our proof involves a simple extension of the familiar diagrammatic technique developed by Solow to show convergence to balanced growth [2]. Finally, a neat economy of exposition is achieved since the diagram can be used to illustrate both convergence to balanced growth and the neoclassical theorem.

Consider the diagrammatic representation of Solow's fundamental differential equation  $\dot{r} = sF(r, 1) - nr$ .<sup>2</sup> Along the  $x$ -axis, we measure the capital-labor ratio; along the  $y$ -axis, output per man. The ray through the origin, with slope  $n$ , represents the function  $nr$ . Draw the function  $F(r, 1)$  which shows output per worker as a function of capital per worker—following Solow, it is drawn to pass through the origin and is convex upwards—i.e., no output unless both inputs are positive, and diminishing marginal productivity of capital. The function  $sF(r, 1)$  lies below the total product curve by the factor of proportionality  $s$ . It shows total saving per man (output per man multiplied by the saving ratio).

All potential equilibrium points for alternative saving ratios at which the economy clicks, at time zero, into balanced growth with a constant capital to labor ratio are defined by the intersection of  $sF(r, 1)$  and  $nr$  and so must lie along the ray  $nr$ . The distance between the ray  $nr$  and the  $x$ -axis then defines all potential total saving per man for all potential saving ratios; in turn, the distance between the ray  $nr$  and the total product curve  $F(r, 1)$  defines all possible levels of consumption per man. In balanced growth, capital, labor, output, and consumption grow at the same constant exponential rate; when consumption per man is maximized at time zero, it is maximized as well into all perpetuity. Theorem: to maximize consumption per man into perpetuity along a balanced growth path, choose that capital-labor ratio (point  $C$  in Figure 1) at which the tangent drawn to the total product curve is parallel to the ray  $nr$ ; i.e., at which the marginal product of capital is equal to the rate of population growth (the slope of the ray  $nr$ ). If we assume competitive imputation allows the marginal product of capital to be identified as the real rate of interest, then at point  $C$ , the ratio of savings to income,  $BC/AC$ , is equal to the ratio of profits to income  $(RS/AC)$ .<sup>3</sup> In no case, however,

<sup>2</sup> In this equation  $r$  is the ratio of capital to labor  $K/L$ , and  $\dot{r}/r = \dot{K}/K - \dot{L}/L$ . Let  $\dot{L}/L = n$  and  $\bar{K} = sF(K, L)$  where  $s$  is the savings ratio. Then  $\dot{r} = rsF(K, L)/K - nr$  and by the property of homogeneous functions, this can be written  $\dot{r} = sF(r, 1) - nr$ . Cf. Solow [2, p. 69].

<sup>3</sup> Along any balanced growth path, the real rate of interest  $RS/OC$  stands in relation to the natural rate of growth  $BC/OC$  in the same ratio as does the relative share of capital  $RS/AC$  to the savings ratio  $BC/AC$ . The former ratio  $RS/BC$  is the present discounted value of the returns to investment when the discount factor is taken to be the natural rate of growth (the rate of growth of labor in efficiency units). James Tobin has recently advocated the natural rate as the appropriate social rate of discount free from the taint of time preference in the sense that an indifference curve relating this year's consumption to next year's consumption per unit of efficiency labor is symmetrical around a 45 degree line through the origin [1] [3]. For Tobin, the flow of innova-

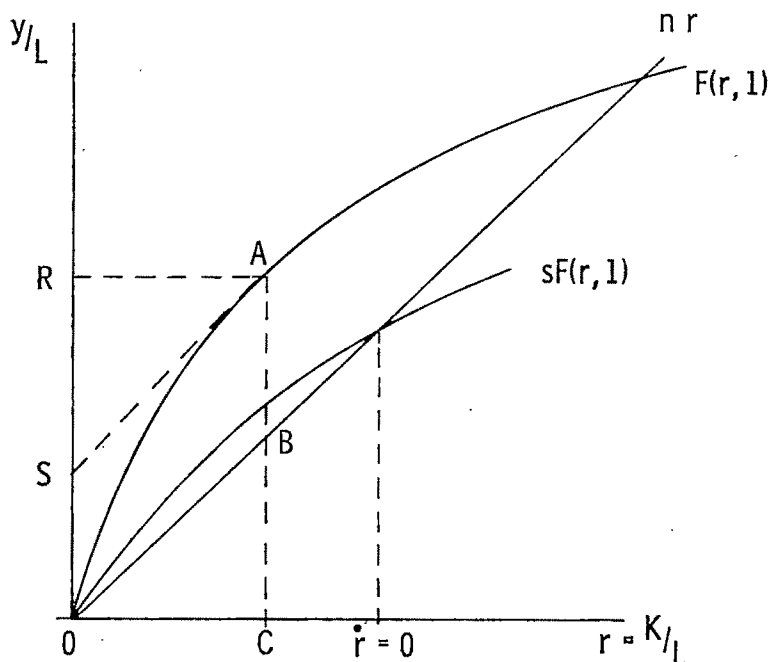

FIGURE 1

should the theorem be made to depend on capitalists' saving all their profits and workers' consuming all their wages. The theorem is best regarded as defining the counterpart for a growing economy of classical capital satiety. In the classical case, in the absence of population growth and technological change, capital satiety takes place when capital deepening along a given production function reduces the marginal net product of capital to zero. Similarly, when the natural rate of growth is positive, capital satiation takes place when the economy clicks into balanced growth with a capital-labor ratio which reduces the marginal net product of capital to equality with the natural rate of growth. To push capital deepening further is to purchase an increment to output per man at the expense of a still greater increment to savings per man and a permanent reduction in consumption per man. This can unequivocally be ruled out as wasteful. It is, given our assumptions, the logical counterpart in a growing economy of pushing the accumulation of capital in the classical stationary state to the point where the marginal net product of capital is negative.

Up to this point, the analysis has dealt solely with population growth. Our diagram is capable, however, of handling the case of Harroldian neutral

---

tions and the growth of population are independent of social policy and so determine a unique natural rate. If these variables are themselves influenced by social policy, no unique natural rate exists which can be taken as the rate of discount.

innovations which leave relative shares unchanged. The contribution of Harrodian neutral innovations to output is measured by the growth of output which occurs at a constant capital-output ratio and a constant labor force. Under constant returns to scale, if output and capital both grow at  $z$  per cent, neutral technological change operates as though the labor force of given efficiency were growing at  $z$  per cent; or that a given labor force is  $z$  per cent more efficient so that labor, measured in efficiency units, is growing at  $z$  per cent.<sup>4</sup> For purposes of this analysis, all that is needed to take account of innovations is to measure labor in efficiency units. The natural rate of growth is then the sum of the increase of labor in natural units plus the increase in output per man. This total defines labor's growth in efficiency units. In balanced growth, the ratio of capital to labor measured in efficiency units is constant, while the capital, output, and consumption are increasing at  $z$  per cent per unit of labor measured in natural units. The problem is exactly the same as before: to maximize consumption per unit of efficiency labor, the ratio of capital per unit of efficiency labor must be such as to reduce the marginal net product of capital to the natural rate of growth—i.e., to the growth of labor measured in efficiency units.

<sup>4</sup>When innovations are Harrodian neutral, the production function at time  $t$ ,  $F_t(K, L)$  can be written  $F_0(K, H(t)E)$  where  $H(t) > 1$  so that each worker at time  $t$  is equivalent to  $H(t)$  workers or, alternatively, labor of given quality can be thought of as growing at  $H(t) - 1 = z$  per cent.

The analysis could in the special case of a Cobb-Douglas function be extended to innovations which raise the marginal products of all factors in equal proportions for all possible input combinations—i.e., Hicksian neutral innovations. For, in this special case, the Harrodian and the Hicksian definitions of innovations are equivalent and the analysis can proceed as before. However, recent empirical work supports the conclusion that the elasticity of substitution is less than unity and it does not seem worth while to incorporate this special case into the analysis.

### Equity Yields, Growth, and the Structure of Share Prices: Comment

In an interesting article in this *Review* [2], Burton G. Malkiel devotes most of his paper to three subjects: the construction of a model of stock price determination which takes into account expected growth in earnings and dividends; second, the use of this model to estimate the market discount rate on a

"representative standard share" in the stock market; and third, on the basis of certain assumptions, the further application of the model to explain deviations in the prices of growth shares from the general level of stock prices (or, more precisely, deviations in the respective price-earnings ratios). While the article gives many valuable insights into the problems involved, it should be pointed out that the basic model presented by Malkiel had been developed before and that the principal assumptions in his two main applications seem questionable.

Malkiel shows that, if dividends, earnings, and prices grow at the same percentage rate in perpetuity, the market rate of discount (or the rate of return required by investors in stock) is equal to  $r = D_0/P_0 + g$  where  $D_0/P_0$  represents the current dividend-price ratio and  $g$  the growth rate. An equivalent result was obtained much earlier by Gordon and Shapiro [1], who showed under the same assumptions that if dividends were paid and discounted continuously at the annual rates  $D_t$  and  $r$ , the market rate of profit ( $r$ ) is equal to  $D_0/P_0 + g$ . Since dividends are normally paid quarterly and growth rates are typically measured (by Malkiel as well as others) annually, the "true"  $r$  for estimation purposes lies in between the two formulas, but the difference in any case is trivial. Subsequent to the Gordon-Shapiro article, I presented an identical formula to that developed by Malkiel and showed that if the terminal price-earnings or price-dividend ratio is assumed equal to the initial ratio, the above formula holds for any finite time period.<sup>1</sup> I stated that I believed that this assumption represented a good first approximation for most companies for most periods of time so long as one does not take too short a period.

The only significant difference I can find between Malkiel and his predecessors in the development of the above formula is that he seems to assume that certainty (in knowledge of future dividends and prices) is required for its validity. This assumption does not appear to be necessary, and it is not clear why it is made. While it can be argued of course that under uncertainty the warranted price of a share cannot be determined from the expected future flow of return without further knowledge of the dispersion around expected return and the effect of such dispersion on the market discount rate, market price is known in Malkiel's model which he uses to estimate the market discount rate of a standard share. It would seem appropriate (or at least preferable to the available alternatives) to use the model to determine the implicit market discount rate associated with the mean values of expected future returns. This rate would reflect investors' collective reaction to the uncertainty attached to such future returns. Presumably, there is little interest in using stock market data to compute market discount rates under certainty unless the untenable assumption is made that the interest rate on a perpetuity is better obtained from the stock market than from the bond market. Even if such an assumption is made—and there is no indication that Malkiel is so doing—the market discount rate he derives for a representative standard

<sup>1</sup> See my Technical Appendix in [3].

share would still have to be adjusted somehow for the difference in risk between a very-long-term bond and the representative stock.

Turning next to his use of the model to derive this market discount rate for a standard share, he states "It will be seen that a given standard earnings multiple uniquely determines this rate" [2, p. 1010]. This thesis—which is repeated throughout his analysis, is basic to many of his conclusions, and might be considered the main point of departure in this article from previous work—is in my opinion incorrect, though it follows from his assumptions. Malkiel's "demonstration" that this discount rate "uniquely can be determined once the standard earnings multiple is known" [2, pp. 1011-12] simply consists of noting that, once constant payout is assumed,  $D/P$  is known if  $P/E$  is known, and that  $g_s$  is "taken to be a constant," where the subscript  $S$  refers to the standard share. The assumption of the constancy of  $g_s$  avoids the problem rather than meets it. It is extremely difficult to measure  $r$  simply because it is extremely difficult to measure  $g$ .

There is no obvious reason to presuppose, as Malkiel apparently does, that fluctuations in  $E/P$  or  $D/P$  for the standard share are matched by fluctuations in  $r$ , which is implied by the assumption of a constant  $g$ . Actually  $E/P$  or  $D/P$  and  $g$  are likely to be strongly inversely correlated not only for individual securities as implied by Malkiel where growth is measured over short periods of time, but it is also true for individual securities over long periods and more important for representative stock over time. Thus for individual securities I have found that the average 1960-62 price-earnings multiples for each of 64 Moody's stocks (included in the income, growth, and utility indexes) were fairly strongly correlated with the annual compound rate of growth in earnings from 1946-48 to 1960-62 ( $R = .82$  for all stocks combined and  $.63$  for utilities alone).<sup>2</sup> This is not necessarily inconsistent with Malkiel's model even though the growth rates used are very long term. However, similarly for the stock market generally, I would suppose that the drastic reduction in the  $E/P$  ratio over the postwar period was associated with a substantial increase in investors'  $g$  expectations. Malkiel apparently believes (though he is not explicit on this) that the drastic reduction in  $E/P$  reflects a similar decline in  $r$ —and this during a period when interest rates on long-term U.S. government bonds nearly doubled. I would expect that a rise in  $g$  or the expected future growth rate was fully as important as any decline in  $r$ . Any significant change in the growth rate of the standard share ( $g_s$ ) would appear to contradict Malkiel's basic assumption.

Now it might be maintained that as a result of his assumption of certainty, which I have questioned earlier,  $g$  can be assumed known and hence a constant. However, not only would such an assumption make the model largely irrelevant to its subsequent (and almost any other) application, but it would still be as meaningless to say that  $(P/E)_s$  determines  $r$  as to say  $g_s$  determines  $r$ .

Malkiel's subsequent use of his assumption of a constant  $g_s$  to draw cer-

<sup>2</sup> See [3] for the basic data.

tain conclusions about the relative stock market behavior of growth vs. nongrowth issues might also be questioned: viz., "But a falling level of share prices also implies that the dividend yield on standard shares tends to rise. Therefore, the discount rate used to convert the future value of the growth stock to present worth increases" [2, p. 1016]. The second sentence quoted no longer follows if  $g_s$  is not a constant, and a similar statement may be made about the conclusion: "Hence, *ceteris paribus*, the price-earning ratios of nondividend-paying growth stocks may be expected to fall by a greater percentage rate than those of ordinary shares." The verbal demonstration as well as the mathematical proof [2, p. 1029] assumes that the standard  $P/E$  multiple is independent of  $g_s$ . The conclusion that growth stocks are inherently more volatile than standard issues is probably valid but not for the reason given. The  $P/E$  ratio of the growth stock is probably more volatile than the  $(P/E)_s$  of the standard share because  $g$  is more volatile than  $g_s$ , and it is also possible that  $r$  is more volatile than  $r_s$ —if growth stock is regarded as more risky than standard issues and if the risk element in the market is more volatile than the pure interest rate.

In his actual derivation of a specific market discount rate for a representative standard share (which rate he applies subsequently to value growth shares as well), Malkiel assumes that for the stock market generally investors believe that the terminal  $(P/E)_s$  ratio is likely to be the same as the current ratio, so that only  $g_s$  has to be estimated to obtain  $r_s$ . For this purpose, he assumes an annual growth rate of 2 per cent in recent years for the Standard and Poor's Industrial Stock Average which is taken to represent the standard share. It seems doubtful that so low a growth rate could be justified on the basis either of investors' expectations during this period or of past growth. The basic rationalization given for this low growth rate is the growth in earnings for the most recent five-year period available (1957-62) and the result implied by Cowles Commission data from just after the Civil War to the middle of the 1930's [2, pp. 1018-19].

It is difficult, however, to find any brokerage literature which indicated so low a growth expectation during recent years. Moreover, if reliance is placed on the more objective statistics, the Cowles Commission data spliced to the comparable Standard and Poor industrial indexes show annual increases of 2.4 per cent in earnings, 2.7 per cent in dividends, and 3.7 per cent in stock prices from 1872-74, just after the Civil War, to 1961-63, centering the beginning and end of year values to eliminate some of the short-run movement in prices;<sup>3</sup> and increases of 4.4 per cent in earnings, 3.9 per cent in dividends, and 5.1 per cent in stock prices from 1895-97, just before the Spanish-American War, to 1961-63. The recently published data of the University of Chicago Center for Research in Security Prices show a 9.1 per cent average annual rate of return on a portfolio of New York Stock Exchange stocks bought in 1926 and held through 1960, which is generally

<sup>3</sup> It might also be pointed out that the low growth rates in earnings and dividends in the early part of this period were associated with very high earnings-price and dividend-price ratios, which again suggests an inverse correlation between  $g_s$  and  $(D/P)_s$ , or a positive correlation between  $g_s$  and  $(P/E)_s$ , instead of the independence Malkiel assumes.

consistent with (though somewhat lower than) the Standard and Poor Industrial Stock Indexes over this period showing stock prices up by somewhat over 5 per cent per annum and earnings and dividends by 4 per cent. The growth experience since the mid-20's therefore seems quite consistent with that since the latter part of the nineteenth century. The experience of reported earnings over the five years through 1962 probably understates the true rate of growth in earnings as a result of the changed depreciation procedures and related devices for reducing book profits in recent years and is substantially less than the growth rate achieved in 1963. Malkiel may have had in mind some adjustment for the effects of general inflationary pressures—i.e., increases in the prices of goods and services—on the growth rates in earnings, dividends, and stock prices, but he does not mention this problem, and the figures he quotes do not seem to be adjusted in this fashion.

Finally, Malkiel applies his market discount rate for a representative standard share, derived in the manner indicated, to determine the warranted price-earnings multiple for growth stocks at two recent points of time by assuming that after certain specified periods of above-average growth the recent  $P/E$  ratio of the growth stocks will revert to the recent  $P/E$  ratio of the standard stocks (and the growth rates of the two types of stock, it is assumed, will similarly coincide). The above-average growth rates assumed for specified periods are generally those reasonably consistent with recent performance, and the periods to which above-average growth rates are applicable are generally taken to be quite short, though the implications of other assumptions are also spelled out. While all the assumptions which are required for Malkiel's earlier analysis, and which I have criticized above, apply here as well, it should be noted that one additional assumption of some importance is introduced in this last part of his paper which might also be questioned, viz., that the market discount rate for growth stocks is on the average the same as for standard issues.

More precisely, Malkiel states that "there should be no clear risk premium difference between growth and ordinary shares . . . for two securities which are equally risky in all other respects" [2, p. 1019]. While this may or may not be true if above-average growth is being projected a year or two in advance, I doubt that it is true on the average or in any operational sense when substantially above-average growth is projected for much longer periods (though it should be noted he apparently considers three to five years the maximum number of years permissible for projecting above-average earnings).<sup>4</sup> It might be possible to make this statement true in some nonopera-

<sup>4</sup> Actually, if *any* above-average growth rate  $g > g_s$  is projected in perpetuity, which might be regarded as consistent with substantially above-average growth for any appreciable period, then Malkiel's basic condition for a growth stock, viz. that

$$\frac{D_0}{P_0} + g > \left( \frac{D_0}{P_0} \right)_s + g_s,$$

would imply that  $r > r_s$ , indicating a positive risk premium difference between growth and other shares. This, of course, does not imply that  $g > r$  in perpetuity, a possibility Malkiel rejects for obvious reasons. The result  $r > r_s$  could not occur under conditions of certainty, but neither could  $r_s > i$  where  $i$  is the pure interest rate.

tional sense if "equally risky in all other respects" is suitably defined. The case Malkiel presents to illustrate his point, involving "the unreliability of the dividend payment of so august a security as United States Steel" as contrasted with "the much less risky . . . extraordinary rate of growth by International Business Machines Corporation," does not seem to be too relevant to a consideration of two securities "which are equally risky in all other respects," including for example vulnerability to cyclical declines in earnings and dividends. In the recent 1961-62 stock market decline, U.S. Steel was one of the relatively few "august" nongrowth stocks which declined proportionately more in price than such growth stocks as IBM.

In his determination of the warranted price-earnings multiple for growth stocks in recent years, Malkiel again introduces the requirement of certainty for the validity of his analysis: "We find that to justify the market price for these issues at the market peak (in 1961), an investor would have to be certain of extraordinary rates of growth (typically larger than had ever been achieved in the past) for a very long period of years" [2, p. 1022]. This seems to be incorrect since, as he has noted earlier, "Our empirical internal rate of return is not a 'pure' yield, for it includes an allowance for the risk inherent in holding a standard industrial share" [2, p. 1019].

His further inference from this analysis—that an excessive number of years of extraordinary growth would be needed to justify the 1961 peak prices—also seems to me to be questionable on the basis of the data presented. The years of growth he finds needed at the rates experienced over the past five years by these growth stocks ranged from four to eight and averaged somewhat over five [2, p. 1023]. The main rationale for his belief that these are excessive, apart from the implications of compound arithmetic, is that "ordinarily five years should be considered the absolute maximum for the investment horizon" and that it represents the maximum horizon used "by financial analysts in attempting an analytical forecast of earnings." At least for utilities, I have seen 10- to 20-year forecasts. With only moderately higher than average growth, lengthening the time horizon in this manner has a major impact on warranted price or implied market rate of discount. Thus a well-known 20-year forecast of a 5 per cent annual growth in earnings per share for the electric utilities made in 1960, with an initial  $P/E$  ratio of 18, implies a discount rate slightly over 8 per cent if the growth rate reverted to even 3 per cent at the end of the period. This is only a moderate reduction from the 8.8 per cent discount rate implied by a 5 per cent growth in earnings in perpetuity (with the same dividend payout ratio of somewhat below 70 per cent in both cases).

I find it difficult to believe even for nonutilities that the analyst is (or should be) only concerned with an "absolute maximum" of the next five years, in spite of the fact that his estimates beyond that point admittedly have a substantially larger margin of error than his near-term estimates. On the other hand, though I am dubious about Malkiel's reasoning on this point, his conclusion implying unduly high prices of growth stocks at the 1961 peak is of course consistent with the subsequent course of events. My own

interpretation is that growth-stock investors in late 1961 were effectively projecting higher than average growth rates for much longer periods than implied in Malkiel's application of his model, but that the market discount rates for standard as well as growth stock were significantly higher than those he derived (for reasons which I have presented earlier). The growth-rate expectations for the particular stocks Malkiel selected almost certainly declined subsequently and may not have fully recovered by the time of the following bull market (1963-64). However, it is not possible to tell what happened on balance to market discount rates from the preceding boom to 1963-64, though they probably first rose and then declined.

### Equity Yields, Growth, and the Structure of Share Prices: Comment

The article on this subject by Burton G. Malkiel in the December, 1963 issue of this *Review* [2] presents a mathematical model for estimating present and future values of "growth" and other common stocks that constitutes a step forward, despite its serious flaws. The model may have some predictive value, but it does not provide a reliable basis for evaluating current levels of share prices as claimed by Malkiel. Especially interesting is his treatment of growth as a factor separate from the earnings rate; his use of an "apparent marginal efficiency of investment" concept; and the manner in which he utilizes a common-stock index to develop "normalized" values for the price-earnings multiplier, the earnings growth rate, and the marginal efficiency of investment.

Comparison of individual multipliers and growth rates against those of a common-stock average taken as a norm is a well-known method which is relied on, for example, in the latest edition of the widely quoted work, *Security Analysis* [1, Chs. 30-31, 37-39].<sup>1</sup> However, the authors use the

<sup>1</sup> The authors find from past data that the appropriate basic multiplier for both the Dow-Jones Industrial Average and Standard and Poor's Composite Index is 15 for current earnings, and 13 for future earnings (average for the next seven years). Thus the DJIA was estimated at 572 for early 1962, or 13 times estimated average earnings of \$44 for 1962-68. This compares with a Central Value estimate of 534. Actual market value of the DJIA in January, 1962 was 705, far above the "intrinsic" value, implying a greatly overvalued market at the time. Curiously enough, Malkiel's critical comments about this book have reference to the older 1951 edition.

older, nonmathematical approach, and in part at least the purpose is different, namely, a search for "intrinsic" value by deriving a fixed, true price-earnings multiplier from historical data; or by determining a "Central Value" through the use of an arbitrary multiple ( $1\frac{1}{2}$  times) of the "basic interest rate."

Malkiel does not fall into the trap of assuming that there is some underlying, true price-earnings multiplier and related capitalization rate that apply to a stock average at all times.<sup>2</sup> He recognizes that the investing public changes the discount rate it places on future earnings from time to time, and that this will alter the multiplier. He does err, however, in assuming that in a given period "warranted" normalized prices can be established for growth stocks to serve as a standard for gauging over- and undervaluation of the latter. This implies incorrectly that the market rather typically miscalculates the values of growth stocks, presumably mainly because earnings plus growth are discounted too many years ahead. A sounder position, it seems to me, is that the market *typically* reflects with reasonable accuracy the warranted values of both growth and nongrowth shares in terms of their earnings prospects. Prices of common stocks rest on discounted future earnings. The highly organized, competitive stock market, with its strong nucleus of informed buyers and sellers, performs this difficult function of price determination very well for most stocks. Errors in assessing the earnings prospects of particular stocks are by no means unknown, and future developments are at times unforeseen or their importance is misjudged. Yet the market's assessment of future prospects is usually close to the mark, as is attested to by its reliability as a lead indicator of cyclical declines. In the case of growth stocks, with a seemingly assured rapid expansion of earnings in the years immediately ahead, this expectation is justifiably reflected in current prices based on higher than average price-earnings multipliers.

### I. *Malkiel's Model*

Let us now examine Malkiel's model, in particular certain questionable assumptions and concepts underlying it. Then it will be appropriate to propose an alternative model that I consider to rest on sounder theoretical ground and to work more satisfactorily.

1. It is assumed, following the position taken by J. B. Williams [3, p. 55], that the present value of a share of stock is equal to the sum of its discounted future dividends. This emphasis on dividends runs counter to the growing reliance of the investing public on earnings rather than dividends in appraising common-stock values and prospects. Earnings are rightly recognized by informed investors as being more fundamental because they represent not only current dividend-paying power, but also, through investment of undistributed profits, a means for future growth of earnings

<sup>2</sup> A leading advisory service, Value Line, seems to have fallen into this trap. The service expects a catastrophic decline in the "flagrantly overvalued" stock market in the not so distant future. Price-earnings multiples are expected to revert to historic levels well below those prevailing in the past decade, and the dividend yields on major stock averages are expected to rise above the average yield on bonds [5, p. 400].

and dividends. As we shall see later, empirical data support the position that share prices are based on future earnings, not dividends.

Because of this reliance on dividends in Malkiel's model, he finds it necessary to treat nondividend-paying growth stocks as a special case, and to devise a modified model to deal with them. This is unnecessary if dividends are ignored and reported earnings are used as the basis of value for *all* common stocks, as is shown below.

2. In the model,  $r$  is defined as the apparent marginal efficiency of investment of the "representative share," equal to  $d_s + g_s$ . Here the representative share is Standard and Poor's 425 Industrial Stock Average;  $d_s$  is the ratio of the dividend at the close of the current year to the existing price of the standard representative share; and  $g_s$  is the rate of growth of earnings. Conceptually, it would seem that  $r = e_s + g_s$  would be more appropriate, as marginal efficiency should have reference to that rate of discount which equates the sum of future earnings (not dividends) with present value. There is also the objection that  $r = d_s + g_s$  assumes that the growth rates for earnings and dividends are identical. This is not supported by the facts, even for stock averages, and is particularly wide of the mark in the case of individual stocks.

Malkiel argues that  $r$  can be uniquely determined, once  $m_s$ , the standard price-earnings multiplier, is known. Since

$$(1) \quad d_s = \frac{D_s(1 + g_s)}{P_s},$$

and  $P_s = m_s E_s$ , by substitution

$$(2) \quad d_s = \frac{D_s(1 + g_s)}{m_s E_s}, \quad \text{or}$$

$$(3) \quad m_s = \frac{D_s(1 + g_s)}{E_s} \bigg/ d_s.$$

That is,  $m_s$  is equal to the payout ratio

$$(4) \quad \frac{D_s(1 + g_s)}{E_s}$$

(assumed to be constant) divided by the dividend rate based on next year's dividend. Alternatively,  $m_s$  may be viewed as determining  $r$ . With a fixed payout ratio, if  $m_s$  is known, and  $r = d_s + g_s$ ,  $r$  is also given, once  $d_s$  is determined.

This cumbersome procedure for determining  $m_s$  and  $r$  evidently seemed necessary to Malkiel because he assumed that dividends are the basis of share values and therefore equated  $r$  with  $d_s + g_s$ . Actually,  $r$  usually can be obtained directly by a simple method that avoids making inaccurate assumptions of a constant dividend payout ratio and identical growth rates for  $E_s$  and  $D_s$ . The method is to calculate the rate of discount which makes

the current value of a share (representative or other share) equal to its value in some earlier year. The formula here is

$$(5) \quad P_s = \frac{P_n}{(1+r)^n}, \quad \text{or}$$

$$(6) \quad (1+r)^n = \frac{P_n}{P_s},$$

where  $P_s$  is the share's value in the earlier period (treated as present value), and  $P_n$  is the accumulated value to the current period. The equation may be easily solved for  $r$ , the marginal efficiency of investment. Then, if we assume that  $r=e+g$ , as suggested earlier, once  $r$  is obtained,  $e$  is also determined, as  $g$  is known. Further, since  $P/E=m$ , and  $E/P=e$ , where  $E$  is next year's earnings,  $m=1/e$ , and  $P=E/e$ .

3. The formulas developed by Malkiel for the derivation of a "normalized"  $P$  and  $m$  for each individual growth stock seem to rest on two misconceptions. The first is that the market tends to overvalue growth stocks, making it necessary to adjust  $P$  and  $m$  downward to more realistic or warranted levels. If, as I deem more plausible, the market typically establishes prices for growth shares that reasonably reflect future prospects, taking account of the uncertainties with which it must deal, there is no justification for "normalized" prices and earnings multiples.

A second misconception is that  $m$ , the average price-earnings multiple in recent years for a representative share, is a significant norm against which the  $m$  of any given growth share should be compared. The misconception here arises in part from a failure to recognize that each individual stock has its own characteristic price-earnings multiple for a given period, against which its current earnings multiple more appropriately should be compared; and partly from a failure to realize that a stock average has no special significance, other than being an average, since *all* stocks, growth and non-growth, are capitalized on the basis of their earnings and growth rates, with due allowance for supposed differences in degree of risk and uncertainty.

4. Malkiel's concept of the structure of equity prices appears to be influenced by the second misconception noted under (3) above. He regards that structure as being such that the normalized price of a nondividend-paying growth stock is some multiple of the price-earnings ratio for the representative standard share. For reasons already indicated, it would seem more plausible to hold that the structure of equity prices rests on differences in earnings and growth rates, after allowance for their regularity and persistence, without regard to representative shares and normalized prices. A stock average is itself dependent on the structure of equity prices prevailing at a given time.

## II. *The Proposed Alternative Model*

Granted that the criticisms made above of Malkiel's model are well taken, what changes are needed to make it more satisfactory? Obviously, several

substantive changes are in order: the use of earnings in place of dividends as a basis for capitalization; the elimination of normalized prices for growth stocks; and a redefinition of  $r$  in terms of earnings and growth. Direct calculation of  $r$  for a substantial number of common stocks convinces me that  $r$  is indeed based on  $e+g$  instead of  $d+g$ .

The proposed alternative model may be summarized as follows:

$$(7) \quad P_n = \frac{E(1+r)^n}{e} = mE(1+r)^n,$$

the future value of a share, where  $E$  is next year's earnings,  $e$  is  $r-g$ ,  $g$  is the average growth rate of earnings per share, and  $r$  is the marginal efficiency of investment.

$$(8) \quad P = \frac{P_n}{(1+r)^n} = \frac{E}{e} = \frac{mE(1+r)^n}{(1+r)^n} \quad \text{or} \quad mE.$$

$$(9) \quad r = e + g,$$

the rate of discount required to equate present and future values of a share of stock.

$$(10) \quad m = \frac{P}{E} = \frac{1}{e},$$

the average price-earnings multiplier for recent years, using current price to next year's earnings.

Formula (8) above differs from Malkiel's

$$(11) \quad P = \bar{m}_s \frac{E(1+g)^n}{(1+\bar{r})^n}$$

for nondividend-paying growth stocks in several important respects. It is applicable to both growth and nongrowth stocks. For compounding earnings  $(1+r)^n$  is used, not  $(1+g)^n$ , since accumulated future value depends on the combined earnings and growth rates. Finally, the  $m$  is used in place of  $\bar{m}_s$  (the  $P-E$  ratio for a representative share), and  $(1+r)^n$  is used in place of  $(1+\bar{r})^n$ . Malkiel's  $\bar{r}$  is the marginal efficiency investment for a representative share, and equals  $d_s+g_s$ , not  $e+g$ .

Now, let us first apply the model to the Dow-Jones Industrial Average (DJIA). Taking  $P_n$  as 767, the Average at the close of 1963, and  $P$  as 454, the Average for the last quarter of 1957,  $r=9.1$  per cent.<sup>3</sup> Owing to the wide fluctuations in the earnings growth rate, and the exceptionally high earnings in 1957, the rate was calculated over a longer period. For 1953-63,  $g=3.9$  per cent, and for 1948-63,  $g=3.6$  per cent. While both figures are close to several recent estimates, the lower one was taken so as to be on the conservative side. [1, pp. 454-56]. Accordingly,  $e=9.1-3.6$  or 5.5 per cent, and  $m=18.2$ .

<sup>3</sup> On a quarterly basis,  $r=8.8$  per cent.

At the close of 1963, the anticipated federal tax cut made it plausible to assume that  $E$  would rise 5 per cent, from \$40 in 1963 to \$42 in 1964.<sup>4</sup> Thus we have

$$(12) \quad P_3 = \frac{42(1.091)^3}{.055} = 992,$$

the estimated DJIA three years hence; and

$$(13) \quad P = \frac{992}{(1.091)^3} = 764,$$

the estimated present value of the DJIA for the close of 1963, compared to the actual  $P$  of 767. In March 1964,  $E$  for the year of 1964 was commonly being estimated at roughly \$44–\$45. Taking  $E$  at \$44, by formula  $P=800$ , which is the same as the actual value of  $P$  in early March.

Our alternative model applies also in cases where earnings show no growth or are actually declining. Obviously where  $g=0$ ,  $e=r$ ; and if  $g < 0$ ,  $e < r$ , as a negative  $g$  is subtracted from  $r$  to obtain  $e$ . In the case of the Dow-Jones Railroad Average (DJRA), earnings have gradually declined. For 1953–63,  $g=-.045$ , and for 1957–63 it is  $-.034$ . Taking  $g=-.04$  as an approximation, and computing  $r$  from the DJRA for the last quarter in 1959 and 1963, we have  $e=.0386-(-.04)=.0786$ , and  $m=1/.0786=12.7$ . Using Value Line's estimate that  $E$  for 1964 will total \$14.20, then  $P=14.20/.0786$ , or 181 for the last quarter of 1963. The actual  $P$  for that period was 179.

Inland Steel illustrates the case of a stock where  $g=0$ . There has been no discernible earnings growth since 1955. Using end-of-year prices for the period 1954–63,  $r=.0723$ . Taking  $g=0$ , we have  $e=r=.0723$ , and  $m=13.8$ .  $E$  is estimated at \$3.25 for 1964. This yields  $P=44$  at the close of 1963, identical with the actual  $P$  at that time.

Application of the model to individual stocks presents greater problems because prices and earnings tend to fluctuate more erratically, and in some instances data are limited to too few years. Where necessary, however, it is possible to derive  $r$  indirectly, by estimating  $e$  from the average or characteristic  $m$  of the stock for recent years. Table 1 presents measures obtained by applying the model to six well-known stocks, American Telephone and Telegraph, General Public Utilities, and four of the growth stocks used by Malkiel in applying his model, namely, International Business Machines, Litton Industries, Perkin Elmer, and Howard Johnson. Estimated prices for the latter three stocks based on Malkiel's model are given for comparative purposes. In applying the model, it was assumed that the market was still below its peak. Hence,  $\bar{m}$ , was taken at 18.2 in place of his 20.3, and  $\bar{d}$ , and  $\bar{r}$  were raised to 3.1 per cent and 5.1 per cent respectively. His estimated growth rates are used, though his growth rate for Perkin Elmer seems much

<sup>4</sup> Up to the close of 1963 the DJIA earnings for that year tended to be underestimated, at about \$40. A subsequent official estimate is \$41.11 [4, p. 55].

too high. The "normalized" prices thus estimated are considerably above actual prices. By contrast, our model yielded an estimated  $P$ , calculated as of the close of 1963 or beginning of 1964, that was exceedingly close to the actual  $P$  in all but one case, as Table 1 shows. Note that there is no evidence of the gross overvaluation that was supposed by some to exist at the time. Actual prices were close to estimated prices calculated on the basis of historical relationships in the recent past.

Malkiel called attention in his article to the volatile nature of growth-stock prices and used estimated peak and trough standard and growth-stock price-earnings multiples to illustrate the extent of fluctuations that take place. I prefer a different method of showing this, in the hope that further

light will be cast on the disconcertingly large shifts that at times occur in growth- and even nongrowth-stock prices.

Assume that later this year a cyclical contraction is expected, i.e., is anticipated to take place early in 1965, so that  $E$  is expected to fall to \$41 instead of rising to \$44 by then. If the recession is viewed as minor,  $e$  would probably rise only slightly, with a corresponding decline in  $m$  and a larger drop in  $P$  to the level where  $E/P$  would equal the new  $e$ . For instance, if  $e$  rose for the DJIA to 6 per cent from 5.5 per cent,  $m$  would fall from 18.2 to 16.67, and  $P$  would drop from, say, 800 to 685 or under. An expected sharper contraction might cause  $e$  to rise to, say, 7 per cent, with  $m$  falling to about 14.3 and  $P$  adjusting downward to 41/.07, or approximately to 585, a fall of some 215 points in the Average, or nearly 27 per cent. Assuming no change is expected in the growth rate,  $r$  would rise at least temporarily to 10.6, implying an accelerated rate of increase of  $P$  in the subsequent cyclical expansion.

A larger percentage decline is likely to take place in growth stocks. For example, if IBM stood at 560, and  $E$  was expected to drop from, say, \$14

to around \$12, and  $e$  rose from 2.5 to 3.4 per cent,  $P$  would fall to about 350, some 37.5 per cent. Some growth stocks would of course fall more precipitously than IBM because a sharper drop in earnings is expected or because future growth seems less certain.

#### Equity Yields, Growth, and the Structure of Share Prices: Reply

In their two comments, Irwin Friend and Roy C. Cave have attacked several assumptions of my valuation model and have questioned both the applications of the model and its principal implication concerning the greater volatility of growth stocks. Before turning to the major points of disagreement between the authors and myself, it would be useful to emphasize the major purpose of my article as well as the questions to which my analysis was *not* addressed. I was not attempting to evaluate, predict, or even suggest the determinants of the level of stock market prices. Nor did I offer, or ever claim to present, a full-uncertainty analysis of share valuation. Moreover, I never considered the empirical section of the paper to be, in any sense, a test of the model—the particular calculations performed were purely illustrative.

It is well known that individual securities may differ in risk and that investors may alter their estimates of earnings growth rates. My purpose was to show that, apart from these factors, it is possible to define a meaningful structure of share prices at any point in time, and that the level and structure can change in the absence of changes in growth rates and risk premiums. Perhaps the most interesting and important results of this analysis concerned the volatility of growth stocks. Abstracting from all the reasons usually adduced to explain the greater volatility of growth stocks, such as those suggested by Friend and Cave, I found an important additional reason to expect such a pattern. Most growth stocks are "longer in duration"<sup>1</sup> than standard issues. The greater volatility of growth stocks is perfectly analogous to

<sup>1</sup> A holder of standard (dividend-paying) shares gets more of his money back sooner than a holder of low- or nondividend-paying growth stocks. Growth stocks are thus longer in "duration" to use Macaulay's [7, pp. 44-53] measure of maturity.

the well-known observation that long-term bond prices are more volatile than short. The intention of my analysis was to uncover just such structural relationships which have yet to be treated in the literature and which are quite interesting in their own right.

### I. Professor Friend's Comment

In view of the general purpose of my article, it would appear that many of Friend's comments which quarrel with my particular illustrative calculations or which claim that, in fact, my *ceteris paribus* assumptions may not hold are, to some extent, beside the point. The more important questions are whether or not Friend has successfully overturned the principal theorems of the model. Consequently, my response will largely be confined to these questions.

#### A. The Volatility of Growth Stocks and the Constancy of the Standard Growth Rates

Friend's major argument is built on the observation that, in fact,  $g_s$  (the growth rate for standard shares) is not likely to be a constant, but rather is a major explanatory factor of the level of share prices ( $m_s$ ). Hence he concludes that my model is inadmissible because it assumes  $g_s$  to be a constant. In particular, he implies that the theorems stating that the values of growth stocks are inherently more volatile than standard issues do not hold because a change in  $m_s$  does not necessarily imply a change in  $r$  (the apparent marginal efficiency of the representative standard share), as I assumed [8, p. 1012]. Although he admits that my volatility conclusions may hold in reality, he believes they hold not for the reasons implied by my model, but rather because the public's estimates of  $g$  (the anticipated growth rate of growth stocks) may themselves be more volatile than are estimates of  $g_s$ .

Friend's assertion that  $g_s$  may vary and hence may be a major determinant of the level of share prices is quite plausible, as I have stated [8, p. 1027]. While it was not my original purpose to deal with this possibility, I agree it would be worth while to incorporate this assumption into the model. First, it should be noted that allowing  $g_s$  to vary does not destroy the applicability of the model in determining a structure of share prices at any time. In fact, if, as Friend suggests, the projected standard-security growth rate ( $g_s$ ) at the December, 1961 market peak was higher than 2 per cent, then my judgment about the overvaluation of growth stocks is supported *a fortiori*, since the growth rate of growth stocks would have had to be correspondingly greater to provide any justification for the high market prices that then prevailed. Had the standard-security growth rate been higher, the standard discount rate would have been higher, and the implicit growth rates for my sample of growth stocks would have been even larger (and/or the growth periods longer) than I had suggested.

More important, all the important theorems of the model still hold. It is not necessary to assume (as Friend does) that estimates of prospective growth rates of growth stocks fluctuate proportionately more than growth rates

of standard issues to conclude that growth stocks will be more volatile than standard issues (although anticipations may indeed follow such a pattern, as I mentioned [8, esp. p. 1027]). It can be shown that these volatility relationships hold even when  $m_s$  varies only in response to equiproportional changes in all growth rates.<sup>2</sup> Thus, even accepting Friend's assumption, the principal conclusions of the model are not upset.

While my results can thus be extended to the case where the level of share prices depends upon anticipated growth rates, there were, nevertheless, good reasons to examine the effects of *ceteris paribus* changes in  $m_s$  that are not associated with any alteration in investors' estimates of  $g_s$ . Indeed, it is pre-

<sup>2</sup> This can be most easily demonstrated for nondividend-paying growth stocks. In this case [see 8, p. 1029] the "warranted" price-earnings multiple ( $m$ ) is given by

$$(1) \quad m = m_s \frac{(1+g)^N}{\left(1+g_s + \frac{D_s(1+g_s)^N}{m_s E_s}\right)^N}$$

where  $g$  stands for the growth rate of earnings per share for the growth stock over the next  $N$  years, and  $D_s$  and  $E_s$  are the dividends and earnings of the standard share for the year just past. In accordance with Friend's assumption we let the standard earnings multiple ( $m_s$ ) be a function of the standard growth rate.

$$(2) \quad m_s = f(g_s), \quad f' > 0.$$

We further assume that investors tend to raise and lower growth estimates for all securities proportionately, i.e., when investors double their estimate of the growth rate for the representative standard share, they double the estimated growth rate for all securities. Note that this demonstration does *not* require that  $g$  be more volatile than  $g_s$ . We then have

$$(3) \quad g = h(g_s),$$

specifically  $g/g_s = K$  where  $K > 1$  by our definition of a growth stock. Accepting Friend's assumption that  $m_s$  changes in response to changes in anticipated growth rates, the new condition for growth stocks to be more volatile than standard shares becomes

$$(4) \quad \frac{1}{m} \cdot \frac{\partial m}{\partial g_s} > \frac{1}{m_s} \cdot \frac{\partial m_s}{\partial g_s}.$$

The percentage change in the price-earnings multiple for a growth stock must be greater than that for a standard security in response to a generalized increase in expected growth rates. Differentiating and evaluating the relevant expressions, we find that (4) holds since

$$(5) \quad \frac{1}{m_s} \cdot \frac{\partial m_s}{\partial g_s} = \frac{f'}{m_s}, \quad \text{while} \quad \frac{1}{m} \cdot \frac{\partial m}{\partial g_s} = \frac{f'}{m_s} + \Delta$$

where  $\Delta > 0$ .

In the case of dividend-paying shares, I was, as before [8, pp. 1016-17], unable to deal with the relevant expression analytically. I was forced instead to examine ranges of representative values of the function for different values of the variables to determine whether my results still hold under Friend's assumptions. These calculations support the conjecture that most dividend-paying growth stocks will still be more volatile than standard issues even when  $m_s$  changes only in response to changes in  $g_s$ . However, as I conjectured earlier, dividend payments lessen the volatility of growth stocks. Moreover, the volatility of dividend-paying shares increases with the growth rate and the growth horizon. I am greatly indebted to R. E. Quandt who programmed these calculations.

cisely because my model abstracts from many real-world phenomena that *ceteris paribus* changes in the standard price level are to be expected. One could list a number of important occurrences in the postwar period which are ignored by the model and which could be expected to affect the standard price level. Perhaps most important, there has undoubtedly been a significant reduction in investors' perceived appraisals of the risks involved in holding common stocks. The mildness of postwar business fluctuations has gradually convinced investors that the disastrous losses incurred by holders of common stocks in the early 1930's are no longer likely. Consequently, the risk premium demanded by investors holding common shares has probably declined significantly in the postwar period. If such risk premiums tended to be variable in the short run, *ceteris paribus* changes (in terms of my model) in the standard price level would be more often the rule than the exception.

Many additional factors, not treated by the model, have affected the postwar level of share prices. Important legal and institutional developments, including the growth of pension and mutual funds and relaxation of the limitations on common-stock investment on the part of life insurance companies, have significantly broadened the market for common shares. At the same time, the ability to avoid taxes on capital gains unrealized until death has probably contributed to a locking-in of a substantial portion of the existing stock of equities.

Finally, a change in the market rate of discount for nonrisk streams will affect the standard price level by changing an important component of the total return. Of course, as Friend has pointed out, the postwar rise in  $m$ , occurred despite a substantial rise in the riskless yield. Nevertheless, he agrees that (for the postwar period) a decline in  $r$  was fully as important as a rise in  $g$ . Our differences on this score are then, at most, matters of degree, and it is certainly admissible and apposite to inquire into the effects of changes in the level of share prices which are not accompanied by changes in  $g$ . Thus it appears that Friend's major criticism of my article has misfired. There is sufficient ground for interest in a model that employs the assumption of *ceteris paribus* changes in the standard price level to which Friend objects. Moreover, the principal conclusions of the model continue to hold even on Friend's own assumptions.

#### B. *Uncertainty and the Horizon Period*

Most of Friend's other comments deal with two (related) matters: the treatment of uncertainty and the horizon period. He questions why the original model was cast in terms of perfect certainty and argues against the application of the standard discount rate to growth stocks without the addition of a premium to account for their greater risk. Such a premium, he claims, can explain the relative volatility of growth stocks because "the risk element in market evaluations is more volatile than the pure interest rate." Finally, he objects to my use of a limited horizon period for projecting extraordinary growth rates.

As mentioned above, my analysis never claimed to offer a general model for the valuation of shares under uncertainty, although some elements of uncertainty were later added to the analysis. It was because my model addressed itself to other questions and because no generally acceptable method for dealing with uncertainty exists that the abstract model was couched in terms of perfect certainty. It is one thing to believe that an extension of the model to cope with uncertainty would leave particular findings untouched, but quite a different matter to build a full-uncertainty valuation model.<sup>3</sup>

When I undertook to apply the model, I decided to "ignore any risk differences resulting solely from the fact that the expected yield from one security may come largely from capital appreciation, whereas the yield from the second is expected to be derived largely from dividend payments." My argument to support that position relied on the dividend-irrelevancy theorem of Modigliani and Miller [9]. I readily admitted, however, that growth stocks may still be riskier than standard shares [8, p. 1019n.]. The matter will never be settled outside a full-uncertainty valuation model and an attendant empirical investigation.<sup>4</sup> Inability to deal fully with uncertainty is the most important lacuna of my model. Nevertheless, as I shall argue presently, my use and alteration of the horizon period can serve as a means for taking account of at least some elements of uncertainty.

In my analysis I utilized the concept of a *limited* horizon period over which extraordinary growth could be projected. The finite-horizon method for dealing with uncertainty has always figured prominently in the literature of investment theory and has attracted a considerable following among practitioners. Economists have pointed out that this technique leaves much to be desired for, among other things, it ignores any prospective receipts after the cut-off date and can be shown in some circumstances to lead to rather absurd rankings of investment projects. But the growth-stock model employed a finite-horizon device which was rather less crude. If investors' horizons are limited as a practical matter to five years, this does not imply that all receipts to the shareholders after the horizon period are ignored. All that is implied is that only normal growth is projected after the cut-off period.<sup>5</sup>

<sup>3</sup> I am guilty, however, of using the word "certain" carelessly in the passage cited by Friend [8, p. 1022]. I meant that an investor would have had to "expect" extraordinary growth rates. I had specifically argued that the portion of the analysis in which the quoted passage appeared did not assume certainty.

<sup>4</sup> I am well aware that my example comparing U.S. Steel and IBM is unconvincing. It was chosen only because a leading investment advisory service had assigned equal risk ratings to the two companies. Both Friend and I have been guilty of frequently resorting to casual empiricism in our references to uncertainty. We will be able to shed light on these more intractable problems of investment analyses only through the route of painstakingly building up the empirical evidence.

<sup>5</sup> Three reasons were adduced for suggesting a five-year horizon for industrial corporations, purely as a practical matter. First, the workings of compound arithmetic render highly implausible the projection of extraordinary growth rates for prolonged periods. Moreover, the typical historical pattern for growth companies has involved only limited periods of extraordinary growth. Finally, I argued that, in practice, financial analysts are unable to forecast for longer periods. The fact that utilities, which are, in effect, guaranteed a satisfactory rate of

But, in fact, I admitted later that no maximum reasonable horizon exists, only a *putatively reasonable horizon*, a variable characteristic of market sentiment at any time [8, p. 1024]. I argued that such horizons underwent rapid changes and that these changes must be accorded an important role in any explanation of the greater volatility of growth stocks. The point of this discussion is not that I claim to have incorporated into the model a generally satisfactory method for coping with uncertainty. At best the finite-horizon method deals with only a part of the problem. The point is rather that this method is, I believe, partially descriptive of the actual valuation process and, most important, that it generates precisely the same type of results as would changes in the discount rate ( $r$ ). Thus, Friend's "alternative" argument, which explains part of the greater volatility of growth stocks in terms of the volatility of the risk discount, is really analogous to my analysis which relied heavily on changes in the *putatively reasonable horizons* used by investors in valuing growth stocks.

### C. *The Nature of the Assumptions of the Valuation Equation*

Both Friend and Cavé have been critical of my growth-stock-valuation equation: Friend impugns its originality, while Cavé attacks its fundamental logic. Both criticisms are wide of the mark and reflect a lack of understanding of the differences in assumptions between my model and previous ones.

Friend suggests that my basic model is not original and cites writings, including his own, in which a similar model was developed before. I had always recognized and stated that the model was built on the work of J. B. Williams [10]. Nevertheless, one of the original aspects of my model is that the earnings multiple for a growth stock reverts back to a standard level after the period of extraordinary growth is completed, and I thus avoid "counting the same trick twice."<sup>6</sup> A fundamental difference between my valuation equation and those that preceded it, including Friend's, is my view that it is improper to assume that the future price-earnings multiple will be the same as today's.

Indeed, it is my use of the "standard" earnings multiple in the valuation equation to which Cavé most strenuously objects. He claims that the price-earnings ratio used for comparison should be the characteristic historical multiple for the individual stock in question. Here Cavé commits what might be called, the "Value Line" fallacy. The popular Value Line investment service relies on the assumption that each stock has its own characteristic earnings multiple against which the current multiple should be compared to detect cases of over- and undervaluation.

---

return by the regulating agencies, can often project their earnings for much longer periods, is an exception rather than a refutation of my argument.

<sup>6</sup> Compare this with the following assumption in Friend's model [2, p. 23]: "The one important assumption is that investors expect that the price earnings multiple . . . at the end of the period when they are going to liquidate their investment will be the same as when they invest. This is a very reasonable assumption, certainly a very good first approximation for most companies for most periods of time."

To illustrate the difficulty which besets such an approach, suppose a company is expected to enjoy an interval of extraordinary growth after a period of stable earnings. By using its average past-earnings multiple as an appropriate standard, an investor would be induced to avoid the stock if, as would be likely and consistent with my model, its multiple rose in anticipation of the company's favorable prospects. Now assume the growth period ends after several years and the company's earnings become stable again. My model suggests, *ceteris paribus*, that the price-earnings ratio should revert back to its former (nongrowth) level. But investors who utilized a past average-earnings multiple (including the high multiples which anticipated the extraordinary growth) as a norm, would tend to maintain the higher historical multiple and thereby realize inferior returns. This would be the typical history of such an approach; underestimating the worth of the issue before and during its dynamic growth period and overestimating its worth after the growth period has terminated. Of course Friend's model is subject to precisely the same criticism. It is not applicable to growth stocks since it implicitly embodies the "Value Line" fallacy by continuing to value growth stocks at extraordinarily high price-earnings multiples even after the termination of unusually high growth rates.<sup>7</sup>

## II. Professor Cave's Comment

Cave's fundamental objection to my model is that one shouldn't even try to establish "warranted" normalized prices for growth stocks. He says, "This implies, incorrectly, that the market typically grossly miscalculates the values of growth stocks." Not only is this statement a *non sequitur*, but Cave cannot go on to insist that market prices reflect warranted values unless he has independent evidence of what these warranted values are. I believe [8, p. 1027] that actual market values do oscillate about a structure of prices that does a reasonably good job of equalizing net yields. Nevertheless, I question the plausibility of Cave's view, that at any time "the market typically establishes prices for growth shares that reasonably reflect future prospects."<sup>8</sup> On the contrary, investors characteristically change the prices they are willing to pay for particular growth prospects. For example, during December, 1961, International Business Machines' shares sold at 580. Six months later the same shares sold at 300. Currently IBM shares are again selling at approximately 580, adjusted for recent stock splits. A check with several influential Wall Street security analysts convinces me that throughout this period there

<sup>7</sup> Only for the representative standard share did I use the assumption of a constant price-earnings multiple. In this way I avoided having to predict future market levels. This was why I called the discount rate derived, the *apparent* marginal efficiency. In this case it is true that both Friend [2] and Gordon and Shapiro [4] had previously developed my equation (3) [8, p. 1011].

<sup>8</sup> Cave adduces the stock market's "reliability as a lead indicator of cyclical declines" as proof that the "market's assessment of future prospects is usually close to the mark." A recent study by M. Hatanaka [6, Ch. 12] suggests rather that stock-price indices are relatively poor indicators of actual business activity. A record of 55 per cent success in predicting movements of the economy hardly seems to constitute an impressive record of prediction.

was no change in informed professional opinion as to either the short- or the long-run prospects for IBM. This evidence would call into question Cave's explanation for the volatility of IBM which relies on an expected drop in earnings. My model showed how such price variability can be explained even if earnings prospects are not revised.

#### A. *Dividends, Earnings, and the Valuation of Shares*

Cave goes on to claim that I err by emphasizing dividends as the fundamental source of valuation. On the contrary, I emphasized repeatedly the Miller-Modigliani view which treats dividend policy as a mere detail [8, pp. 1007, 1015]. Cave's misunderstanding of this point leads him to a serious error in his own model. The dividend-irrelevancy theorem states that, given the investment decision, dividend payments to current shareholders merely reduce the value of their claim in the enterprise. This is so because additional equity shares in the business (representing an amount equal to the dividend payment) must be sold in order to finance the predetermined level of capital expenditures. This theorem can readily be demonstrated in the context of a dividend model of share valuation. Indeed, Miller and Modigliani themselves evaluate shares in terms of prospective dividends to obtain this result [9, pp. 418-19]. The theorem does not imply, however, that two firms with identical future growth rates of earnings will sell at identical capitalizations of earnings irrespective of their dividend payments. Yet it appears that Cave has failed to realize this.

The underlying logic of Cave's equation (9),  $r = e + g$ , is never made explicit. Nevertheless, it must rest on the assumption that the present worth of a share is equal to the discounted sum of the stream of future earnings.<sup>9</sup> But such an assumption cannot serve as a rational basis for valuation, as has been pointed out by several writers (e.g., [3, pp. 102-3] and [9, p. 420]). The crucial point it neglects is the cost of the additional capital required to maintain the earnings stream at its specified level. The assumed growth of earnings may require the steady reinvestment of all or part of the earnings stream. If two firms have identical expected earnings streams, but one firm can pay out all of its earnings in dividends, whereas the second must reinvest all its earnings to support the earnings stream, a stockholder would always be better off by buying the dividend-paying shares.

<sup>9</sup> Let

$$P = \sum_{i=1}^N E \left( \frac{1+g}{1+r} \right)^i.$$

Summing the geometric progression and solving for  $r$  we obtain  $r = e + g$ , where

$$e = \frac{E(1+g)}{P},$$

the earnings yield based on the earnings for the following year.

### B. *The Apparent Marginal Efficiency of the Standard Share*

Cave then offers a "superior" alternative method of determining the relevant discount rate for the representative standard share. He simply calculates the discount rate that makes the discounted current price of a share equal to its price during some base period. Why Cave ignores the dividend payments that accrue to the holder (and increase his return) is not explained. Moreover, Cave's measure is far more sensitive than mine to the base period chosen for comparison. Starting from 1957 he gets an  $r$  of 9.1 per cent. Had he started from the close of 1958, his  $r$  would have been close to 2 per cent. The problem is that Cave includes in his measure the capital appreciation received since 1957 which resulted from an increase in the price-earnings multiple for standard shares. The last quarter of 1957 represented the bottom of a sharp decline in market values. During 1958 the market prices (and price-earnings multiples) rose sharply. Of course much the same problem besets my measure of standard growth rates. However, the growth rates represent only a portion of the " $r$ " of my model, and they are much less sensitive to changes in the base date than are market prices themselves.

Friend also utilizes a similar type of argument to suggest that my estimate of the standard growth rate is too low. He cites the University of Chicago Study [1] to suggest that average annual gains of 9 per cent were realized on a portfolio of shares bought in 1926 and held through 1960. In the first place, the 9 per cent return assumes reinvestment of dividends. If dividends are withdrawn, the rate of return falls to 6.9 per cent. While Friend may be right that my illustrative growth estimate is too low, it is worth pointing out that this type of evidence can be quite misleading if applied to certain time periods. The Chicago Study's measure of growth rates does not distinguish between growth that results from increases in the earnings and capital gains that result from a decrease in the capitalization rate applied to those earnings. There is no theoretical or empirical reason for believing that past increases in price-earnings multiples can simply be projected into the future. Indeed, such a practice is particularly dangerous because it can easily lead to a "vicious circle": a higher market price serves to justify itself by increasing the past over-all return. It was precisely this kind of reasoning to which Graham and Dodd [5, Ch. 30] attributed the "new-era philosophy" of the 1920's.

### C. *Cave's Model*

Cave finally constructs an alternative model which embodies his criticisms and, consequently, "rests on sounder theoretical ground." His model turns out to be an identity: the price of a share equals the earnings per share times the price-earnings multiple. The appropriate earnings multiple is derived in one of two ways; Cave either uses the characteristic historical multiple for the stock in question, thus committing the "Value-Line fallacy," or calculates the multiple after finding the over-all returns realized over some period in the past, thus opening the Pandora box of problems I mentioned under

II (B) above. Moreover, his entire approach confuses *ex post* with *ex ante* returns. *Ex post* data may reflect in large part errors in estimating future performance. They do not provide a reliable guide for estimating *ex ante* required returns. It is not true that the investor in the common shares of Litton Industries requires a 42.6 per cent return while the investor in Perkin and Elmer Corporation requires but a 21.6 per cent return, as is implied by Cave's Table 1. Finally, as indicated earlier, Cave's neglect of dividend payments leads him seriously astray.

Cave does not even follow a consistent earnings approach to valuation. For the Dow-Jones average he calculates  $r$  over the period 1957-63, but  $g$  is calculated over the period 1948-63. Similarly, in dealing with individual issues, he arbitrarily picks both the time periods and the method of computation to suit his convenience in arriving at his valuations.<sup>10</sup> This makes the remarkable degree of convergence between his estimates and actual market values less surprising than might appear at first glance. Had Cave followed one consistent valuation method (with consistent time periods) he would have seen that his model fails to produce useful results. Cave therefore provides neither a reliable basis for evaluating general market levels nor a useful method for appraising individual common shares.

### Capital-Labor Ratios in Theory and in History: Comment

The prolonged debate over factor proportions during economic development took a new and challenging turn in the article by Professors Fei and Ranis in the June, 1963 issue of this *Review* [6], together with a portion of Professor Ranis' paper at the December, 1962 meetings [16]. These authors propound a doctrine of "capital-shallowing" in the early industrialization of retarded countries and present it with great ingenuity on both the theoretical and the empirical levels.

Most other writers find or assume that such development entails increasing capital-intensity in some degree; and they differ chiefly as to the optimal degree and timing. Fei and Ranis, however, deny both the necessity and the desirability of intensifying capital in the early stages of development. They claim to have found that "capital-shallowing" has occurred in at least one historical instance; they commend that path to investment planners; and they infer that the maximum-employment objective and the maximum-output objective can usually be reconciled along that path.

The present comment seeks to revindicate the principle that ordinarily industrialization requires capital-deepening. The argument will be made first by indicating the methodology of the Fei-Ranis model, then by re-examining and recomputing the Japanese data, by reinterpreting the concept of "labor absorption," and by applying qualitative evidence from the history of Japan, India, and Communist China.

#### I. The Model

The Fei-Ranis article in question here is concerned with the expansion of a relatively small, commercialized "industrial sector," alongside a large subsistence-type agricultural sector whose role during development was examined in an earlier article by the same authors [18], both discussions being elaborated from Arthur Lewis' celebrated two-sector model of economic development under conditions of "unlimited supplies of labor" [9]. The Lewis model, however, does not hinge on the degree or trend of capital intensity within the modernizing sector, since it indicates only that, with given capital and given production functions, the capitalist sector will at most draw from the subsistence sector just so much labor as will bring the marginal productivity of the transferred workers into equality with the low and constant

wage,<sup>1</sup> this wage being set at average subsistence earnings plus a differential necessary to attract subsistence workers to capitalist industry. Fei and Ranis have reformulated this model in abstract taxonomic terms which make explicit the possibilities of capital-shallowing as well as capital neutrality and capital-deepening, within the industrial sector during the developmental sequence. But there is no assurance here that actual market conditions, together with available technologies, will permit instances of each of these possibilities to occur. Consequently our authors turn to actual experience and rest their argument on the differential between two cases: namely, Japan as an instance of "successful" development, allegedly marked by capital-shallowing up to 1917, in contrast to India, which during 1949-60 is said to show capital-deepening accompanied by developmental lag.

These data are then used to demonstrate the importance of "innovations" in the process of labor absorption, with the sheer accumulation of capital playing a minor role. This is done by the residual method, whereby a part of the actual increase in industrial employment is attributed in direct proportion to the increase in capital stock (with no allowance for improvements in quality of capital, and on the assumption of constant returns to scale); and the remainder of employment growth is attributed to "innovations" (which the authors analyze conceptually into elements of "labor-bias," "innovational intensity" and "demand elasticity for labor," but which they use in practice as a single catchall extending well beyond technological change). Because of this residual method, the results of the whole model are affected by whatever biases creep into the conceptions and the empirical measurement of growth in employment and in capital.

## II. *The Fei-Ranis Estimates for Japan*

The measurement of capital-intensity and of its trends over time always presents stubborn problems of translating the abstract concepts of capital and labor into the mixed and imperfect terms of empirical records (cf. [2]). It is difficult to obtain long series for capital and for labor that are both consistent within themselves and appropriate to each other. It is still more difficult to take account of indirect inputs of these factors (including the capital and labor embodied in imports) or to adjust for qualitative changes over long time-spans (innovations in tangible capital, improvements in human capital). In the case of Japan, the analyst is tempted to seize upon several new series that have recently been published [11] [14] [19] [23] and use them to construct important aggregative relationships. But it is dangerous to draw strong inferences from such series, as Fei and Ranis do, in face of the limitations of the primary data and the heroic assumptions on which they have been worked up [15] [22].

Fei and Ranis have devised a long sequence to represent the capital/labor ratio ( $K/L$ ) in Japan for the sector they label "industrial"—which is in fact the whole economy minus the sector of agriculture and other "primary" ac-

<sup>1</sup>Of course the accumulation of capital in the growing industrial sector will tend to raise the capital-per-capita ratio of the whole economy—abstracting from population growth—but our concern here is solely within the industrial sector.

tivities. To obtain their annual series on industrial capital ( $K$ ), they very ingeniously combined a stock figure with flow data. Beginning with Ohkawa's version of the official estimate of national wealth in 1930 [14, p. 164], and excluding some items as not being industrial capital, they projected it backwards all the way to 1888 by applying Professor Rosovsky's recent estimates of annual investment in Japan [23, pp. 109-10]. In fact, they successively subtracted from the 1930 stock of industrial wealth Rosovsky's figures for annual gross outlays on private nonresidential construction, private durable equipment, and all public investment, after deflating those annual figures for price changes (using Ohkawa's "non-agricultural price index" [14, p. 130], derived from wholesale prices of staple commodities), and then reducing to net terms by deducting a constant ratio of 20 per cent of the annual gross investment to represent depreciation. These procedures obviously permit considerable distortion of the data and understatement of the record.<sup>2</sup> In addition, the authors retained in their 1930 capital stock figure all of buildings and all of inventories; while the annual investment figures, which they subtracted from the 1930 stock, exclude inventories and also exclude residential buildings. We must also note that all the figures used by Fei and Ranis include most of military goods, agricultural equipment, and perhaps a few other categories which are not properly "industrial."

To obtain their industrial work-force figures, however, Fei and Ranis took an even broader scope for the "industrial" category. They simply subtracted persons in the primary occupations from the total of the gainfully occupied in each year. They utilized the Hijikata estimates as presented by Ohkawa, but made no allowance for Ohkawa's criticisms of those estimates as overstating the primary occupations in the early years and correspondingly understating the remainder of the labor force [14, pp. 146-49]. In addition, they were unable to adjust the labor input for the gradual decline of man-hours per worker [3, pp. 137-38], [7, p. 412], nor conversely for the gradual rise in the quality of workers as industrialization advanced.

The net effect of these lines of treatment for  $K$  and  $L$  is to show an excessively large initial figure for  $K$ , to which the authors then add unsuitably small annual increments; while for  $L$  they have adopted an initial figure which is probably too small, and to which they add huge annual increments—indeed, the whole annual increase of the national labor force (since the numbers in agriculture remained nearly constant). Inevitably, as can be seen in Table 1 of the article in question, the annual percentage increase in  $K$  appears small, and grows more slowly at the beginning of the period than later on, while the annual percentage increase in  $L$  looks large, and so the  $K/L$  ratio appears to decline. More precisely, the ratio shows a decline until 1917, when the growing annual investments as measured by these authors finally became large relative to the indicated capital stock at that time, while the indicated growth ratio of  $L$  kept declining almost steadily from 1888.

<sup>2</sup> No attempt was made to adjust for quality improvements over time, an adjustment which would have raised the calculated rate of capital accumulation and its contribution to growth; cf. Solow [24] versus Denison [4]. Fei and Ranis reserve the quality improvements for their category of "innovations," whose magnitude they obtain only indirectly by the residual method indicated above.

Not only are these statistical series defective, but also they do not really measure "successful absorption" of labor in "the industrial sector." The Fei-Ranis procedure lumps tertiary services together with secondary occupations in both  $K$  and  $L$ . Consequently, their "industrial sector" is a nonfunctional mixed bag of relatively high-productivity activities (modern kinds of manufacturing, transportation, commerce and banking, etc.) mingled with the many low-productivity activities (mostly traditional service occupations such as petty trading, manual transport, manual excavation and construction, handicrafts, domestic help, entertainment, etc.) which in overpopulated countries occupy many individuals who cannot find work yielding higher individual income and net social output.<sup>3</sup> The resulting mixed figures, being at most an average of the diverse subgroups, do not represent "successful absorption" for the whole industrial sector, since Fei and Ranis—still following W. A. Lewis—require that "absorption" take place at "the industrial real wage" and not below it (i.e., not at real social marginal productivity approaching zero). Therefore a  $K/L$  ratio based on workers' mere presence in nonagricultural occupations, regardless of productivity, cannot have clear implications as to the sources of Japanese real growth in aggregative terms, let alone implications as to optimal factor proportions for individual projects or for particular industries. Such figures certainly should not be used for comparison with the capital/labor ratios computed by Fei and Ranis for India, where they deal with an "industrial sector" more narrowly defined (i.e., "large-scale manufacturing and mining and small-scale or cottage industries").

### III. *Alternative Estimates for Japan*

Because of the imperfections in the immediately available data, it is not easy directly to remove the biases which have crept into the Fei-Ranis treatment. One approach is explicitly to revert to whole-economy measures, instead of selecting sectors which, while giving the appearance of homogeneity, often prove to be internally inconsistent or externally ill-matched. Perhaps the simplest and safest measure of this kind was made by Ohkawa, who constructed a series on capital per capita for the whole economy of Japan.

For  $K$  he used eight historical estimates of national wealth—after excluding land, consumers' household goods, bullion holdings, the balance of foreign indebtedness, and a few other categories of "nonproductive wealth," and adjusting a few other categories; and after deflating the estimates by a price index of construction costs for some items, and a general wholesale price index for the other items. For  $L$ , Ohkawa used the total population. The results (Ohkawa's variant " $K_1'/N$ ") [14, p. 170] are shown in Table 1. This series shows a strongly rising trend, not a fall, throughout this period since 1905, except for 1917-19. To be sure, the data here do not go back to the very be-

<sup>3</sup> Cf. [11, pp. 131-32]. This phenomenon of overcrowded occupations in the traditional services, with a social marginal productivity approaching zero, has been observed in many retarded countries; cf. [12, Ch. 1]. It should be possible to check directly on this phenomenon in the Japanese record by examining the trend of incomes per capita in the various sectors. Unfortunately, the best estimates currently available, pages 100-115 of the Ohkawa volume already cited [14], are deficient at this point, since for the early years Ohkawa simply linked the whole tertiary sector with the whole goods sector by way of a fixed ratio—which of course begs the whole question.

ginnings of Japan's modernization, and they are not free of serious defects, especially as regards the methods of valuing the stocks and the techniques of price deflation, so that the finding of a generally rising trend is not conclusive.

Another showing that the  $K/L$  trend for the whole economy was upward, rather than downward, is obtained by adapting the Fei-Ranis method of flows applied to a stock, using a broader base to improve the consistency and the matching of these series. This is done by taking Rosovsky's annual figures for nearly *all* investment (counting in the residential construction, although still excluding agricultural improvements and inventory growth because the annual data are not available) and applying them (with the same deflation and depreciation allowances) backwards from the terminal (1930) figure on *all* capital stock (the same used by Fei and Ranis for the "industrial sector" alone); while the denominator of this  $K/L$  ratio is the *total* population. The results of this computation are shown in Table 2, at five-year intervals drawn from the complete annual series. Once again we observe a persistently rising

Coverage of investment figures here includes residential and nonresidential construction and durable equipment in both the private and the public sectors; coverage of 1930 capital stock includes these classes plus current inventories.

trend, which is not appreciably altered by interpolation between the years shown, nor by substituting for  $L$ , in place of total population, the above-cited Hijikata estimates of the total labor force.

If we can accept these findings of a continuous rise in the over-all  $K/L$  ratio, then *a fortiori* we must expect a still stronger rise in the "industrial" sector alone, since it is generally agreed—for Japan as for most underdeveloped countries—that measured agricultural investment per capita tends to lag behind industrial investment per capita.

It would of course be highly desirable to make a direct measure of the  $K/L$  ratio for the industrial sector in the exact or narrow sense if the deficiencies of the present data could somehow be circumvented. One approximation is possible by taking the rate of growth in the stock of durable equipment at years close to the estimates of national wealth used in Table 1 above, and comparing that growth rate to the trend of the industrial labor force; see Table 3. For the former rate of growth, we take Rosovsky's figures for private

gross investment in durable equipment in 1905, 1906, and 1907<sup>3</sup> and after deducting the afore-mentioned 20 per cent for depreciation, we apply the figures in then-current prices to the 1905 stock of durable equipment also in then-current prices;<sup>4</sup> and we do a similar operation for 1913, 1914, and 1915. For the rate of growth in the labor force, we use either the Fei-Ranis series in their "industrial sector" (which is somewhat too wide for our durable-goods category) or Ohkawa's series for secondary industry (which is a little too narrow). In every case, as shown in Table 3, we find that the capital stock so defined was growing faster than the labor force. In other words, the  $K/L$  ratio was evidently rising during this pre-1917 period when Fei and Ranis allege it was falling.

Using the same body of data, we can construct average and incremental  $K/L$  ratios for each period. We find that, in every case, the incremental ratio is far above the average ratio, indicating that the average must have been rising.

Still another indicator may be extracted from data provided by Professor Ranis in an earlier article [17]. Table III in that article (p. 601) provides a  $K/L$  series for a single industry, the cotton-spinning industry in Japan, as shown in Table 4. The ratio given in the last column in Table 4 shows a rising trend in every interval except the first and next to last.<sup>5</sup> Thus the evidence for a single important industry agrees with the trend we have found for the whole industrial sector.<sup>6</sup>

<sup>3</sup>In the stock figure we have left government durable equipment (which includes military goods), also many structures which belong in a construction category. Since the annual investment figures have narrower coverage, the effect is to depress the indicated growth rate of  $K$ —which nevertheless shows up relatively high.

<sup>4</sup>Surely the figure of 21.5 for the first  $K/L$  ratio is far out of line and must be due to gross underreporting of the operatives. Especially lacking in the Japanese statistics are direct reports on the workers in the small-scale shops, which have been a prominent feature of industry in that country from the outset of her modernization and gradual mechanization; cf. [1] [11] [20].

<sup>5</sup>A similar trend for the significant early years 1896-1900 may be found in [7, p. 403], showing horsepower rising faster than work force in mechanized factories, while the nonmotorized workshops were declining in number and in workers.

None of these approaches, to be sure, is the precise and final word on the trend of the  $K/L$  ratio in Japan. Ohkawa, Rosovsky, and others, in current research projects both in this country and in Japan, are reworking the data that are now available. But in the meantime the consensus of the measures shown here seems to be a rising trend of the ratio in Japan's evolution right from the beginning, at least as far back as 1888, with no period of declining ratio from 1888 to 1917, as alleged. In broad contour, the path of rising capital-intensity in Japan parallels that which Fei and Ranis present for India.

#### IV. *Qualitative Evidence*

As the data presented above are not altogether conclusive against the doctrine of capital-shallowing, it may be useful to refer to some qualitative features of economic development. There are only a few ways by which the  $K/L$  ratio might be carried downward in the industrial sector during its development: (a) the premodern  $K/L$  ratio might have been very high—whether due to a capital-intensive technology or due to underutilization of plant capacity—and at any rate higher than the marginal  $K/L$  ratio of the newly introduced modern industries; (b) the initial stage of industrialization might consist mainly in installing projects of high capital-intensity (notably “social overhead capital”), while the second stage concentrates on lower  $K/L$  projects and on fuller utilization of the earlier ones; (c) the industries of high labor-intensity might be expanded more than the capital-intensive industries; (d) in the new industries, whatever their initial  $K/L$  ratios may be, labor might be continuously expanded faster than capital, either by substituting  $L$  for  $K$  or by adding more  $L$  to given  $K$ .

None of these possibilities seems to fit very well the historical experience of most underdeveloped countries, bearing in mind that we are dealing with conditions of surplus labor and are concerned with the expansion of wage-employment industries. The Japanese record, as set forth in [1] [7] [11] [13], among others, gives a particularly bad fit. Indeed, possibility (a) above actually presupposes in the premodern economy a relative scarcity of labor, not a surplus. Possibility (b) would require in Japan a rising  $K/L$  ratio at least into the first decade of the twentieth century, to be followed by a falling ratio during the years when Fei and Ranis allege it was rising (after 1917). As for possibility (c), this runs counter to what we know about trends in labor-intensive small-scale industries (in Japan, some of the old handicrafts expanded but many were destroyed, and others survived and grew only when modernized by some application of additional capital, as further explained below). Finally, possibility (d) requires capital-saving, labor-using innovations in technology, since capitalists, however “paternalistic,” will not hire many workers whose marginal productivity falls below the “industrial wage”; but in fact we observe that even in labor-surplus countries the rational capitalist tends to replace “cheap” labor with machines which prove to be still cheaper (to the firm); thus the surplus labor is left to crowd into service occupations where its marginal productivity approaches zero (cf. [10]).

When we turn to the Japanese practices which Fei and Ranis themselves

cite as means of achieving capital-shallowing in that country, we find that they do not mention our possibility (a), and present some rather a-historical instances of (b), (c), and (d). Their statement [6, p. 301] is that nineteenth-century Japan adopted "labor-using innovations" which "included, among others, the natural survival of modernized cottage-style manufacturing as part of a large-scale industrial complex based on subcontracting arrangements; the speed-up of machines and the adoption of multiple shifts; and the widespread substitution of surplus labor in all sorts of activities peripheral to the machine process proper." Unfortunately, these suggestions treat cross-sectional differentials (i.e., among industries in Japan or in comparisons between Japan and Western countries) as equivalent to historical sequences within Japan. Actually, the mentioned practices were either ancient Japanese labor-intensive methods which were slowly displaced by more capital-intensive methods during the course of industrialization or they were factory practices adopted almost concurrently with the introduction of modern machines (e.g. high-speed, multiple-shift working of machines [7, p. 412]). Rarely were they improvements gradually introduced over the years, as Fei and Ranis seem to believe. In particular, many of the celebrated small-scale industries in Japan—which indisputably used more labor relative to capital than did the modern factories either in Japan or abroad—survived and flourished insofar as their traditional methods were modified to incorporate some elements of modern capital (e.g., pedal-driven and power-driven looms and knitting machines in cottage weaving; improved tools in woodworking; general-purpose lathes in metalworking; bicycles in local transportation, etc.); see [1, Chs. 4, 5] [11, Chs. 3, 4] [20]. In general, labor in Japan was not historically "substituted" for capital in industry in the absolute or displacement sense; labor substituted mainly in the relative or opportunity sense of avoiding still higher capital-intensity during modernization. Thus the fact that the rise of capital-intensity was restrained must not be converted into a belief that capital-intensity was actually reduced. "Successful absorption" of labor in Japanese industry generally entailed some degree of capital-deepening. By contrast, it was *unsuccessful* absorption when labor "substituted" for equipment by desperately crowding into certain service occupations where capital and modern technology were hardly introduced at all, and where marginal productivity approached zero.

Curiously enough, one of the few examples of the labor substitution which Fei and Ranis have in mind is actually to be found in India. The Central Government's recent policy of restricting operations in the large-scale textile mills, in favor of handicraft weaving, was intended to enlarge the volume of employment, and accordingly does promote capital-shallowing for the weaving industry as a whole. But it does not promote efficiency and growth, as attested by the unfortunate effects of that policy upon output and upon incentive to modernize [8, Ch. 3].

On the other hand, there is little basis for comparison of India today with Japan around the turn of the century. A great many present-day features, both

domestic and international, are comparatively more adverse to development in India today, and prevent any simple attribution of India's lag to any greater capital-intensity of her industrial projects. Indeed, Indian industry today has already developed beyond many of the devices which in initial stages of Japanese development were used to restrain somewhat the rise of the over-all  $K/L$  ratio.

In recent history, the most distinct and extreme move toward capital-shallowing is to be found in Communist China, in the "mass labor" program, during the 1950's and especially during the "Great Leap Forward" of 1957-58. Millions of laborers, mobilized on the assumption of extensive surplus labor-time, were put to work for little or no material compensation, and with almost no equipment, not even simple tools in many instances [5]. Assigned to manual construction (e.g., earth dams, irrigation ditches, dirt roads), or to primitive steelmaking (the backyard furnaces), or to agriculture (deep-plowing, close-planting, extermination of crop pests), or other fields of work, these laborers showed substantial early achievements, notably in water conservation [21]. Beginning in 1957, however, the regime evidently went overboard into excessive compulsion of labor-time and into the wrong types of assignments. The resulting disorganization, exhaustion, and waste undoubtedly were major factors in the severe setback of the entire Chinese economy after 1958. It would require too much space here to indicate that the experience of Communist China, tied to particular conditions and policies, is not a complete refutation of the whole Nurkse-Lewis theory of the "under-employment potential." But we can recognize at least that the Chinese effort, under a regime wielding totalitarian power, was far from a success in its own terms. These results do not commend the doctrine of capital-shallowing which is in question here.

The foregoing considerations also throw some light on Fei and Ranis' discussion of India as a country which is below her optimum position in regard to both maximizing employment and maximizing output and could therefore advance along both lines simultaneously by means of a lower degree of capital intensity in new industrial projects. This form of advance may well be available for India, as John P. Lewis [8] and others have insisted. But nothing in the experience of Japan demonstrates that the industrial investment pattern can or must be actual "capital-shallowing"; or that, with the given rates of capital formation and population growth, the new facilities soon will "successfully absorb" more than a small fraction of the total labor supply. Unless domestic saving and/or foreign assistance can be raised very high, we are left with the basic and often very painful choice between maximizing output for the sake of economic progress, and maximizing employment for the sake of welfare and political stability in the less developed countries.

### Capital-Labor Ratios in Theory and in History: Reply

Professor Reubens' comments are directed exclusively to one aspect of our view of development in the dualistic economy in which the rapid reallocation of labor from the subsistence agricultural sector to the commercialized industrial sector represents the essential feature of successful growth. It seems to be his contention that our arguments somehow rest on a "faulty doctrine of capital-shallowing" in the industrial sector of the dualistic economy. We propose to examine this issue from the point of view of the logical necessity of capital-shallowing, its desirability, and its empirical validity in the case of historical Japan.

With respect to the logical necessity of capital-shallowing, as Reubens himself admits, neither the original Lewis model nor ours in any way hinges on the trend of industrial sector capital-intensity over time. Conceptually, capital-shallowing, capital-deepening, or constancy in the capital-labor ratio are all possible and, in fact, compatible with successful development.<sup>1</sup> The question is really one of determining which pattern is more *likely* to lead to successful development and hence more desirable.

In an economy characterized by a scarcity of savings fund and the existence of a large reservoir of surplus labor in the agricultural sector, it follows logically that the more we can "stretch" our industrial capital to accommodate labor productively, the better the economy's chances of escaping the Malthusian trap. The more labor-using industrial production techniques and the industrial output mix, the more workers can be transferred to higher-productivity industrial employment, and the more likely that the country can succeed in achieving economic maturity. The phenomenon of capital-shallowing is merely a manifestation (perhaps an extreme one) of such a successful search for labor-using techniques and product mixes. Although it is by no means clear from his comments, perhaps Reubens also does not dissent from this view of the eminent desirability of capital-shallowing in the course of the industrialization process. Thus his quarrel with us is neither with our theory<sup>2</sup> nor with our policy conclusions; it is with the empirical fact of whether or not a particular case of the adoption of increasingly labor-using technology, i.e. capital-shallowing, has, in fact, occurred in the case of Japan. This then becomes merely a problem of statistical verification—to which most of his comments are indeed directed—and to which we shall now turn our attention.

<sup>1</sup>See, for example, our discussion in relation to Diagram 6 [2, p. 299] to the effect that capital-shallowing does not necessarily mean success and that capital-deepening does not necessarily mean failure.

<sup>2</sup>We should take note of one other item of criticism on the theoretical level, i.e., that we assume constant returns to scale and disembodied technological change. We agree that our "innovations," like Solow's [11], thus become a residual catchall. But we are not aware—perhaps Reubens is—of an empirically satisfactory method of disentangling the various components of output growth which cannot be attributed to changes in the physical factors of production, Denison's interesting work [1] notwithstanding.

With respect to Reubens' criticisms of our data on Japan, we are in full agreement that it would have been desirable to have a better statistical breakdown between the subsistence and commercialized sectors of the dualistic economy. Unfortunately, although the problem is quite clear-cut conceptually, it is not as easy to implement statistically, i.e., it is difficult to distinguish between those portions of tertiary employment which meet the "commercialized" condition (e.g., banks and utilities) and those portions which do not (e.g., personal services and distributive trades). The procedure of permitting "agricultural" and "nonagricultural" to serve as proxies for "subsistence" and "commercialized" can undoubtedly be improved upon if the statistical problem can be solved.

We would respond in a similar vein to Reubens' comments with respect to the inclusion of residential construction in our 1930 capital stock estimates (because no breakdown between residential and nonresidential was available) while such construction was excluded from our investment or flow figures. However, when we do make an attempt to correct the 1930 base year estimates<sup>3</sup> and then apply the Rosovsky investment figures as before, the phenomenon under discussion, i.e., that of industrial capital-shallowing in nineteenth-century Japan, is maintained, although the turning point now appears somewhat earlier (see below) than with our original data:<sup>4</sup>

Year	Industrial Labor thous. <i>L</i>	Adjusted Ind. Cap. mil. yen <i>K</i>	<i>K/L</i>
1888	4,993	7,674.1	1.537
1893	5,980	8,395.7	1.404
1898	7,000	9,494.5	1.356
1903	8,111	10,862.3	1.339
1908	9,234	12,587.7	1.363
1913	10,360	15,239.7	1.471
1918	11,480	18,268.8	1.591

We are thus quite prepared to concede that the data presented are far from perfect and merely suggestive. But Reubens' own alternative estimates leave perhaps even more to be desired and, what is more important, do not support the conclusions he draws from them. Even if we accept his evidence of a rising *K/L* ratio for the economy as a whole, for example, we fail to understand

<sup>3</sup>To exclude residential construction and inventories. The former is accomplished by applying the 1889-1930 breakdown between private residential (31 per cent of total) and nonresidential construction (69 per cent of total) to the 1930 buildings figure.

<sup>4</sup>The same industrial labor-force figures have been used as before [2]. Although Reubens criticizes these figures, taken from Ohkawa [4] and based on Hijikata, as defective—as they are—he apparently, like us, finds them to be the best available: witness use of same in his Table 3. Neither did he apparently follow his own advice and adjust labor inputs by changes in man-hours per worker and in the quality of workers.

why this leads us to expect "a still stronger rise in the industrial sector alone." It seems that Reubens comes to this conclusion because *a fortiori* we may expect agricultural *investment* per head to lag behind industrial *investment* per head; but he has completely disregarded the *a fortiori* equally convincing argument that we may expect the agricultural capital *stock* per head to be much lower than the industrial capital *stock* per head. Thus as the center of gravity of the economy shifts from the agricultural to the industrial sector, industrial capital-shallowing is not only consistent with capital-deepening for the economy as a whole but, in fact, represents the most likely and realistic outcome.<sup>5</sup> It should also be well noted that, while the aggregate  $K/L$  ratio increased by only 11 per cent between 1905 and 1917, it increased by 117 per cent between 1917 and 1930 (after industrial capital-deepening set in), according to Reubens' own figures in his Table 1! Thus, even if there had been no actual capital-shallowing in the industrial sector between 1917, the extent of capital-deepening was certainly negligible as compared with after the turning point, which lies at the heart of our thesis.

Reubens' attempt to produce independent evidence on the capital-labor ratio for the industrial sector only seems beset with the same neglect of a fundamental index-number problem. The "approximations" presented in his Table 3, for example, are derived by letting durable equipment serve as a proxy for capital stock. But the fact that one—relatively minor—component of the total industrial capital stock is growing at a particular rate permits one to conclude absolutely nothing about the growth rate of the total capital stock, and thus, together with the growth rate of the industrial labor force, about the industrial capital-labor ratio over time. In fact, private gross investment in durable equipment represented less than 15 per cent of total gross investment between 1888 and 1905, his initial year [10, pp. 109-10].

Reubens' findings of a rising industrial  $K/L$  ratio are thus entirely misleading. Nor is he able to support this contention by citing the figures previously compiled by one of the authors on capital intensity for the Japanese spinning industry alone [6]. Only by asserting entirely *ex cathedra* that inconvenient figures—in this case average annual data over a five-year period,

<sup>5</sup> Reubens surely must realize that the aggregate  $K/L$  ratio at any one point in time is a *weighted* average of the sectoral  $K/L$  ratios  $(K/L)_i$  and  $(K/L)_a$ , i.e.,

$$\frac{K}{L} = w_i \left( \frac{K}{L} \right)_i + w_a \left( \frac{K}{L} \right)_a$$

where  $w_i$  and  $w_a$  are the weights. To illustrate briefly, let us assume (realistically for Japan) that at the beginning of the period 80 per cent of the economy is subsistence and 20 per cent commercialized, i.e.,  $w_{a1} = .8$  and  $w_{i1} = .2$ , while at the end of the period the proportions are 50-50, i.e.,  $w_{a2} = .5$  and  $w_{i2} = .5$ . Then, given a higher level of  $K/L$  in industry than in agriculture in period 1, e.g.,  $(K/L)_{i1} = 5$  and  $(K/L)_{a1} = 2$ , we have initially  $2.6 = .2 \times 5 + .8 \times 2$ . If we then permit the industrial capital-labor ratio to fall, e.g.,  $(K/L)_{i2} = 4$  (keeping that in agriculture which is not at issue constant, i.e.,  $(K/L)_{a2} = 2$ ), we have  $3.0 = .5 \times 4 + .5 \times 2$  at the end of the period. Thus, not only is industrial capital-shallowing perfectly consistent with aggregate capital-deepening but it is exactly what we would expect to happen.

1886-90—are subject to underreporting and are thus to be disregarded, can he make his point with respect to the pre-World War I period under discussion. Moreover, these data again do not reflect changes in plant and, as Reubens himself must realize [9], it was in the continuing reorganization of plant, via subcontracting, “putting-out” arrangements, etc. that major labor-using technological changes were to be encountered—in this case in the weaving branch of the important textile industry cited.

Finally, let us turn to the so-called qualitative evidence presented in Section IV of Reubens’ comments. At the outset he cites four possible reasons why capital-shallowing may conceptually take place in the industrial sector of the developing economy. We have no quarrel with these—though the force of point (a), dealing with a higher  $K/L$  ratio in the preconditioning period with which our article was not directly concerned, escapes us. In fact, we should welcome the introduction of what may be a useful taxonomic device, were it not for the rather strange uses to which it is subsequently put.

As we understand it, Reubens’ first reason, his point (b), is based on the to-be-anticipated relatively larger role of the relatively more capital-intensive social (and economic) overheads in the initial stage of development. But why should this lead to “a rising  $K/L$  ratio at least into the first decade of the twentieth century, to be followed by a falling ratio”? Reubens seems to be expounding some sort of technological law that the typical developing economy must experience exactly three to four decades of overhead construction to be followed by the expansion of directly productive industrial activities. This surely is an unreasonable view of reality. Granted that roads, railways, and other overhead construction must be undertaken early, their relation to the mushrooming of directly productive industrial activities is certainly not of a discontinuous, sequential nature. There is no reason to assume that growth in the latter, proceeding at a rapid clip virtually from the outset, will not swamp the effects of the former.

Reubens’ second reason for capital-shallowing, his point (c), deals with the possibility that industries of high labor-intensity may be expanding faster than those of low labor-intensity. Again, we agree. But we are less sure of the relevance of the destruction of old handicrafts by modernized small-scale industry of higher capital-intensity. Instead of dealing with the central issue of a likely shift in the product mix as between industries, he appears mainly interested in the possible decline of particular nonviable traditional methods of production within a given industry. It is a fact that historical Japan, especially as she was able to participate more fully in the world economy, found herself in a position to continuously shift her product mix toward the more labor-intensive industries, while importing more and more of the more capital-intensive products required.

Finally, in discussing his third reason for capital-shallowing, point (d), he appears again to be in perfect agreement on the existence of a labor-using innovational potential within a given industry and on the possibility of its exploitation by rational profit-maximizing capitalists. But in virtually the next sentence he rejects either or both of these propositions entirely on the basis of his real-world observations. The relevant evidence is not presented,

but even if it were, it is strange logic to assert that a proposition is faulty just because we can observe contrary practice. In fact, it was the main burden of our argument in reviewing India's performance [2] that the practice of adopting increasingly capital-intensive production functions, either consciously for prestige reasons or unconsciously as a consequence of direct government controls (which serve to undervalue the cost of domestic and foreign capital), proved detrimental to the growth process under conditions of an unlimited supply of labor. Unfortunately, the attitudes and policies described are by no means rare in the contemporary less developed world—and neither are cases of nonsuccess in development, as those of India and Communist China cited by Reubens.<sup>6</sup>

In summary, Reubens insists that labor cannot be continuously "substituted" for capital in the developing economy's industrial sector and that the instances of labor-using innovations cited by us for historical Japan merely represent cross-sectional examples of restraint in adopting more capital-intensive methods that were available. We do not agree—and neither, apparently, does Lockwood:<sup>7</sup>

If Japan's experience teaches any single lesson regarding the process of economic development in Asia, it is the *cumulative* importance of myriads of relatively simple improvements in technology which do not depart radically from tradition or require large units of new investment. . . . Much of the real substance of Japanese economic growth . . . is found in the more modest types of improvements which were more easily and pervasively adopted, more economical in cost, and often more productive of immediate returns in income. For any poor country beginning to industrialize, one of the crucial problems is to introduce and *spread* such innovations as widely as possible [3, pp. 198-99, italics ours].

The adoption of new devices to absorb the surplus agricultural labor force was a continuous process within particular industries; such devices included adoption of double-shifting, the speeding-up of machines, and the gradual replacement of long-staple American by short-staple Indian cotton—i.e., machine-oriented innovations, as well as, and more importantly, continuing at-

<sup>6</sup>With respect to India, Reubens must surely realize—from the industrial profit-maximizing assumption in our model, if not from our entire discussion—that we are *not* advocating the artificial retention of uneconomic Ghandian handicrafts for the sake of creating employment in the welfare sense, but the continuing search for indigenous technological and organizational improvements in response to the pressures of factor endowment (see also [8, p. 770] for a fuller statement). While we have never wished to claim that India faces as easy a task today as Japan did 70 years ago, her chances for success would be much brightened if she undertook to facilitate, rather than hinder, the spread of innovational ideas and impulses across the masses of would-be participants in the development process. With respect to Communist China, we certainly do not believe that the adoption of a strategy of capital-shallowing (concentrated incidentally in agriculture) provides protection against other "bad" policies, e.g., setting up uneconomic backyard furnaces and disregarding peasant incentives.

<sup>7</sup>Rosovsky's [10, p. 11] conclusions are identical: "Rapid growth of output could result from moderate improvements in labor-intensive techniques, small amounts of capital and . . . mostly rapid increases in the labor force, in the form of migrants from rural districts. This is precisely what happened in Japan."

tempts to reorganize the industrial process via more efficient handling and subcontracting routines—i.e., plant-oriented innovations (see [6]). Finally, and undoubtedly of the greatest significance, was the possibility of a continuing shift in the product mix, especially as Japan was increasingly able to explore the world markets for her labor-intensive industrial products. As Rosovsky put it:

... the policy of enforced free trade had very beneficial long-run effects ... Japan was poor in resources and capital; her main assets were a large, cheap and relatively efficient labor force, and considerable entrepreneurial talents. These factor proportions suggested the *development* of industries permitting the use of labor-intensive techniques [10, p. 101].

And Lockwood:

... the demand for Japanese manufactures ... was such that a greater share of production was directed towards particular products and processes which required larger amounts of labor per unit of output [3, p. 184].

For example, the labor-intensive textile industry, which represented 18.2 per cent of national income originating in industry in 1878, represented 26.1 per cent by 1895 [7], and, to cite another indicator of what was happening, commodity exports as a proportion of domestic commodity output rose from 5 per cent in 1878-82 to 15.5 per cent in 1918-22 [5, p. 140]. Though we do not find it necessary from either the theoretical or policy points of view expressed in our article to insist on more than a restraint in the rise of the capital-labor ratio over time, we see no reason to abandon our belief that capital-shallowing actually took place in the Japanese case.

### The Stability of Neutralism: Comment

Professor Hirschman's refreshing treatment of "The Stability of Neutralism"<sup>1</sup> suggests the type of contribution that economic tools can make to the solution of problems in the other social sciences. However, such an excursion into interdisciplinary analysis requires a high degree of precision, especially when new concepts are introduced. When using new concepts care must be taken not to revert to their often imprecise and confusing colloquial connotations; in this instance lack of care resulted in an error in reasoning.

Two concepts—economic independence and political neutrality—were introduced and lack of differentiation between them led to conflict. In his diagrammatic presentation Hirschman represented economic aid on the ordinate and political alignment on the abscissa. Aid is available from both Russonia and Usonia, and each is willing to give a maximum of *OT* tons of gold (Figure 1) to a fully committed nation; *economic independence* may be defined as equal aid for Thirldonia from each of the two big powers. On the other hand, political alignment is measured by the proportionate distribution of the underdeveloped land's votes in the United Nations General Assembly; *political neutrality* is achieved at *ON* when its votes are distributed equally between the two superpowers.

The true meaning of the concepts may best be demonstrated in the case where Russonia and Usonia act symmetrically and do Not Penalize Neutrality. No conflict between the two ideas arises; Thirldonia can maximize the volume of bullion it receives by behaving like a neutralist and demanding economic independence. Referring to Figure 1b in the article (reproduced as Figure 1 below), we find that political neutrality can be achieved without sacrificing economic independence; *OA* tons of gold will be forthcoming from each donor if *ON* votes are delivered to Russonia and Usonia at appropriate times in the General Assembly. In Hirschman's framework this is a stable solution—the concave opportunity locus determined by the policies of the two powerful, industrialized nations will be tangent to a convex indifference curve of the independent and neutralist Thirldonia.

A pitfall in the use of the two concepts arises when one of the powers attempts to take advantage of this stable equilibrium. A change by one of the

<sup>1</sup> This *Review*, March 1964, pp. 94-100.

rich nations (say, Russonia) from a policy of Not Penalizing Neutrality to one of Punishing Neutrality leads to the paradoxical situation that by giving less aid a country can secure more votes in the United Nations. This is illustrated in Figure 2 by a slightly modified version of Professor Hirschman's fifth figure.

In this case, Russonia and Usonia are each contributing *OI* tons of gold for the development of Thirldonia, while Russonia is receiving a larger share

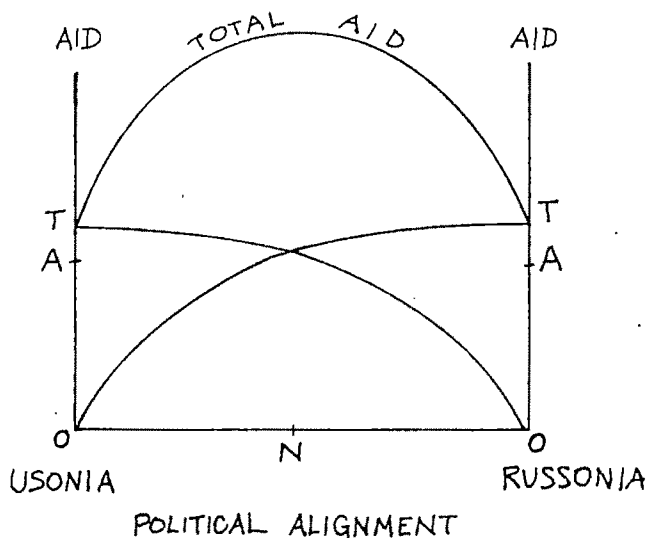

FIGURE 1

of the votes. Clearly, Thirldonia is not politically neutral as Professor Hirschman suggested when he said "If Thirldonia is neutralist . . . it will now select the political position that will equalize aid from both camps and will therefore tend to take up the political position . . . rather close to Russonia." Economic independence and political neutrality are conflicting goals in this example; a move to distribute votes more equally in the General Assembly will force Thirldonia to become economically dependent on Usonia. Therefore, Thirldonia's position will not be as simple as indicated in the note. Although the country cannot influence the total volume of bullion it receives because the policies of the two richer nations determine its opportunity locus, Thirldonia can determine the amount of aid it receives from each donor by its voting behavior. The poor country will be torn between two positions of political neutrality and economic independence, represented by *N* and *I*, respectively, in Figure 2. Thirldonia, with a preference for both political neutrality and economic independence, will be as unhappy about remaining in position *D* as Usonia will be about its loss of support in the United Nations. A move to an intermediate position (*C*) involves a trade-off of less political

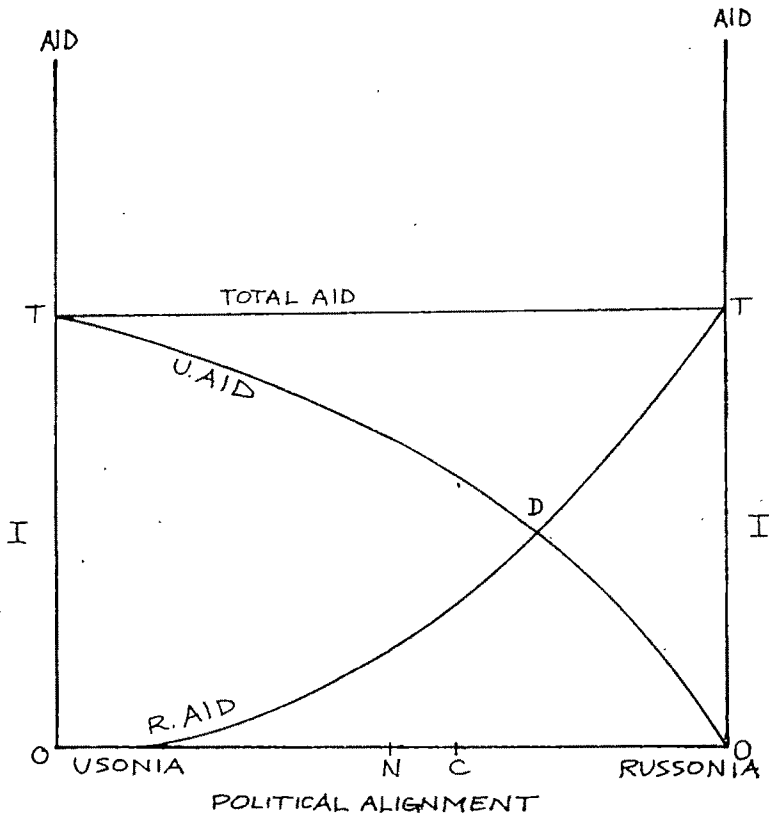

FIGURE 2

alignment with Russonia (more neutrality) for more economic dependence on Usonia (less independence).

Whatever position the neutrally and independently inclined country opts for, the paradoxical situation alluded to by Hirschman persists: Thirldonia favors Russonia as a direct result of its reduction in aid. This, of course, would last only until Usonia reacts to Russonia's policy by adopting a policy Penalizing Neutrality; in this event the world would conform to the unstable combination of Aid-plus-Independence (or more precisely, Independence-plus-Neutrality) and Penalizing Neutrality of Hirschman's schema, that is, minimum development assistance for Thirldonia.

### The Stability of Neutralism: Reply

Mr. Barkin's point is a useful elaboration of my note. The nonsymmetrical aid-giving behavior I portrayed in Figure 5 is indeed likely to set off a conflict between a neutralist aid-receiving country's desire to remain politically equidistant between the super-powers and its propensity to distribute its receipts of aid as equally as possible between them, with the result that some compromise between these two conflicting urges would emerge. Unfortunately, his eagerness to convict me of "an error in reasoning," while achieving for himself a "high degree of precision," obliges Mr. Barkin to surround his argument with an air of unreality by unhelpfully "precise" definitions of neutralism and economic independence. These two concepts cannot be distinguished as neatly as he proposes to do; it would be more realistic, so it seems to me, to speak of two behavioral dimensions of neutralism (or of both neutralism and independence): one could term them the equidistance propensity and the equidistribution (of aid) propensity. After all, it is largely the desire to appear neutral which makes Thirldonia wish to distribute its receipts of a given total of aid as equally as possible between Usonia and Russonia. I neglected one of these dimensions (and quite a few more, I suspect) and am happy to see that my model can handle it with ease.

I take this opportunity to point out that the move of one of two aid-giving powers from a policy Not Penalizing Neutralism (NPN) to one that does (PN)—see my Figures 1b and 5 or Barkin's 1 and 2—bears a striking similarity to the attempt on the part of a trading country to improve its terms of trade by imposing a tariff. A unilateral transition of one of the aid-giving powers from the NPN to the PN policy permits it to reap better "terms of aid"—the country that lowers its aid schedule will paradoxically achieve a political gain. One limitation of this gain lies in the likelihood of retaliation; but, even in the absence of retaliation—and this is a further parallel to the tariff argument—there is an *optimum* point in the unilateral shift from the NPN to a PN policy beyond which Thirldonia is likely to turn away from the aid-policy-shifting power and back toward the country which maintains an NPN policy. Suppose Russonia suddenly decides that, short of complete alignment, no aid whatever will be forthcoming. Then the total aid curve would have the shape of a distorted *V* (somewhat like a square root without the horizontal portion) and, if Thirldonia is neutralist, we would be essentially back at the unstable AI-PN combination: Thirldonia may go all the way back to Usonia, but this is uncertain. A more determinate result is obtained if we follow Barkin and let the equidistance propensity come into play: Thirldonia would then most likely end up at a point somewhere between complete alignment with Usonia and the mid-point on the alignment scale, thus achieving its minimum requirements of nonalignment at

the smallest possible sacrifice of aid. In this fashion, it can be shown that a *radical* policy of penalizing neutralism is self-defeating even, and perhaps especially, in the absence of retaliation.

### Baumol's Sales-Maximization Model: Comment

Professor Baumol has provided an addition to the ever-increasing body of oligopoly theory by substituting sales maximization, with a minimum profit constraint, for profit maximization as the goal of the large business firm. On the basis of a model which he has developed, Baumol claims to be able to show that the oligopolist is in equilibrium at that price and output where realized profit is equal to the minimum acceptable profit. It is my contention that the equilibrium which Baumol derives is only one of many possible constrained output levels.

Baumol's basic static oligopoly model is presented in Figure 1. Output is measured on the horizontal axis, and total revenue, costs, and profits are measured on the vertical axis.<sup>1</sup>

If the firm were a profit maximizer, it would produce  $X_1$  units of  $X$ ; however, Baumol hypothesizes that the firm attempts to maximize sales (total receipts) subject to a profit constraint. Assuming that the minimum acceptable profit is  $\pi_1$ , the firm produces the output  $X_2$  where total receipts are maximized. With an output of  $X_2$  the firm earns  $\pi_2$  profits, which are greater than the minimum required by the stockholders.

Had the minimum acceptable profit been  $\pi_3$  rather than  $\pi_1$ , the firm would have had to stop at  $X_n$  units of output. At output  $X_n$  it would not have been maximizing total receipts; therefore, "two types of equilibria appear to be possible; one in which the profit constraint provides no effective barrier to sales maximization [ $X_2$  units of output with a minimum acceptable profit of  $\pi_1$ ] and one in which it does [ $X_n$  units of output with a minimum acceptable profit of  $\pi_3$ ]" [1, p. 55]. The firm varies output by increasing or decreasing price, and it does so without concern as to the reactions of rival firms [1, pp. 27-32]. Therefore, the oligopolist has an independent price policy which he uses to maximize sales revenue if not constrained from doing so by a minimum acceptable profit.

By introducing advertising into his model, Baumol claims that an unconstrained sales maximization analogous to output  $X_2$  in Figure 1 is not pos-

<sup>1</sup>For the sake of simplicity we shall assume that the firm produces a single product and that it faces a linear demand and cost function.

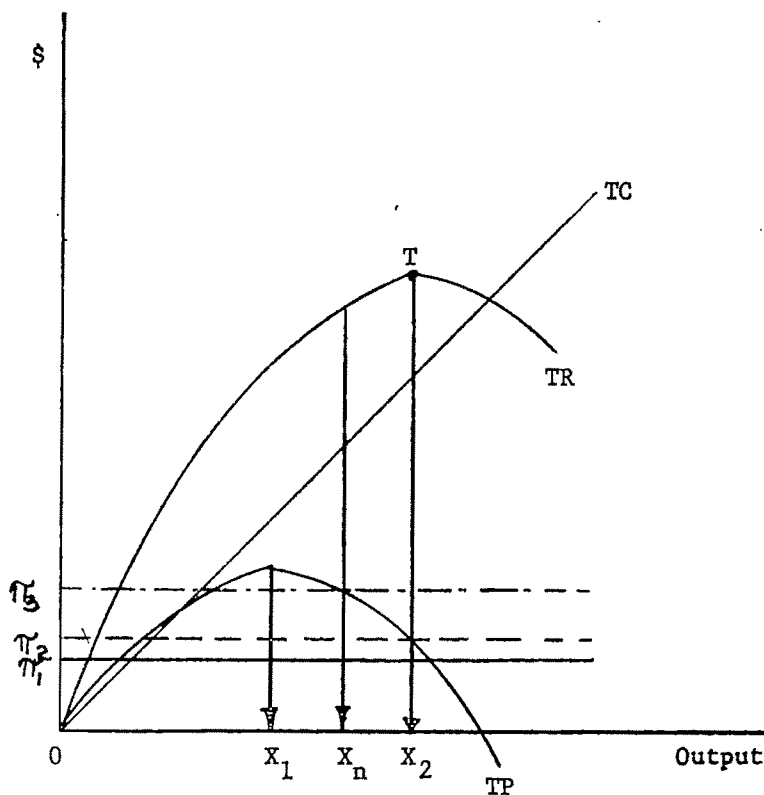

FIGURE 1

sible. In Figure 2 advertising outlay is measured on the horizontal axis with total revenue, costs, and profits on the vertical axis [1, p. 60]. The total revenue curve increases throughout the relevant range because of the assumption "that increased advertising expenditure can always increase physical volume, though, after a point, sharply diminishing returns may be expected to set in" [1, p. 60]. Baumol goes on to say that "unlike a price reduction, a *ceteris paribus* rise in advertising expenditure involves no change in the market value of the item sold."<sup>2</sup> Therefore an increase in advertising outlay must necessarily increase total revenue. "As a result it will always pay the sales maximizer to increase his advertising outlay until he is stopped by the profit constraint—until profits have been reduced to the minimum acceptable level" [1, p. 61]. Baumol does not consider the case where the firm changes price along with the advertising budget, both of which influence output, in order

<sup>2</sup> I assume by this statement that Baumol means price to be given when the firm varies advertising outlay.

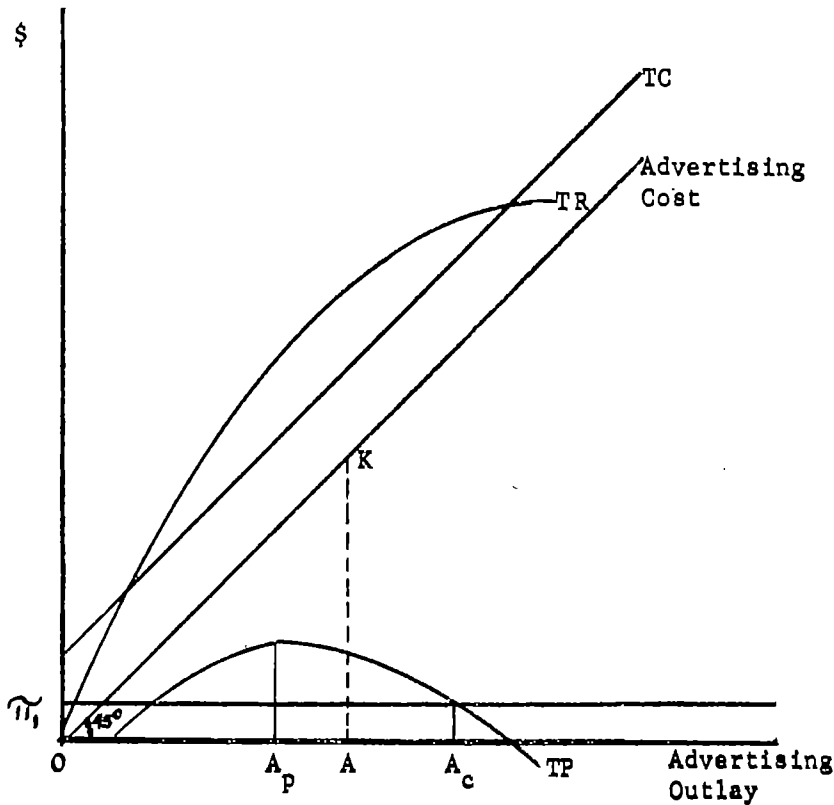

FIGURE 2

to obtain the highest sales revenue given the restriction of earning a minimum profit.

According to Baumol, "the interrelationship between output and advertising decisions now permits us to see the reason for the earlier assertion that an unconstrained sales maximizing output . . . will ordinarily not occur. For if the price is set at a level which yields such an output profits will be above their minimum level and it will pay to increase sales by raising expenditure on advertising, service or product specifications" [1, p. 61]. Once again Baumol fails to mention that sales revenue may be increased by changing price as well as the advertising budget.

It appears that Baumol is saying the firm will produce output  $X_2$  (Figure 1) and charge a price of  $X_2T/OX_2$ . This provides a profit level of  $\pi_2$  which is greater than the minimum acceptable profit of  $\pi_1$ ; therefore, the firm will increase advertising outlay given the price of  $X_2T/OX_2$  (Figure 2). In other words, the total revenue function as presented in Figure 2 assumes a given price. This being the case, there is a different revenue function for every price

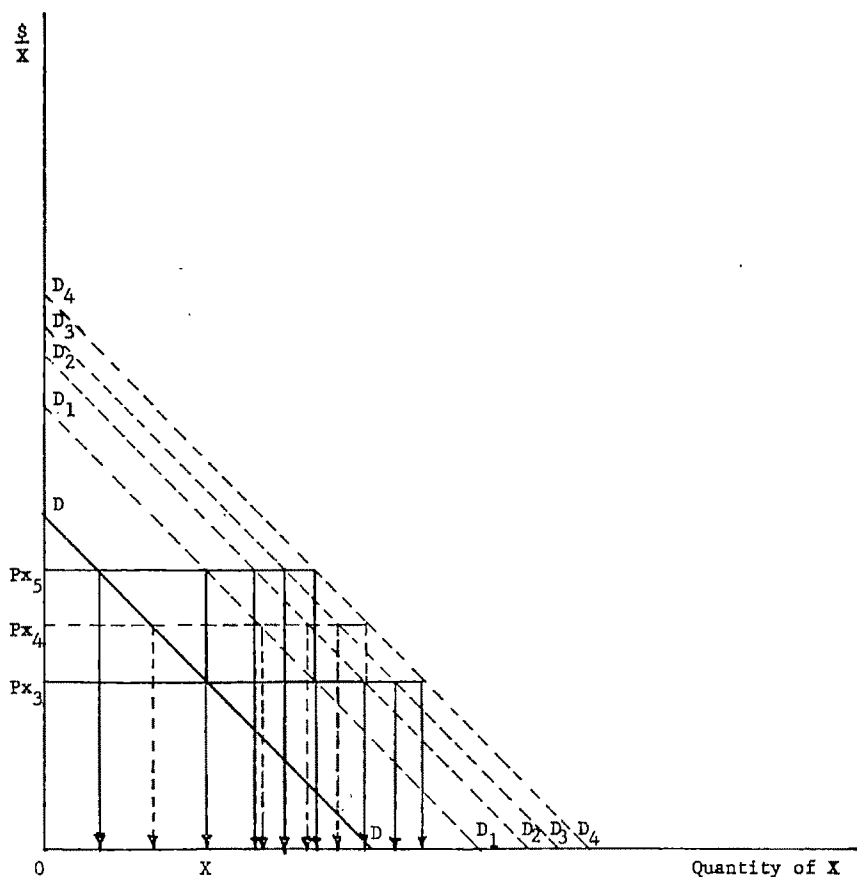

FIGURE 3

which may be assumed. What we have then is a family of revenue functions and, given costs, a family of profit functions.

Let us assume the oligopolist varies advertising outlay one unit at a time<sup>8</sup> which causes the demand curve facing the firm to shift to the right as in Figure 3. The demand curves are drawn so as to be consistent with Baumol's assumption "that increased advertising expenditure can always increase physical volume, though, after a point, sharply diminishing returns may be expected to set in" [1, p. 60]. The firm faces demand curve  $DD$  before advertising and, since it is not constrained from maximizing sales, a price of  $Px_3$  will be charged and  $X$  units sold. Assuming that, at this price and output, the realized profit is greater than the minimum acceptable profit, the firm will

<sup>8</sup>One unit is equal to any total dollar amount we may want to select; however, it is assumed that the advertising budget is increased in equal increments.

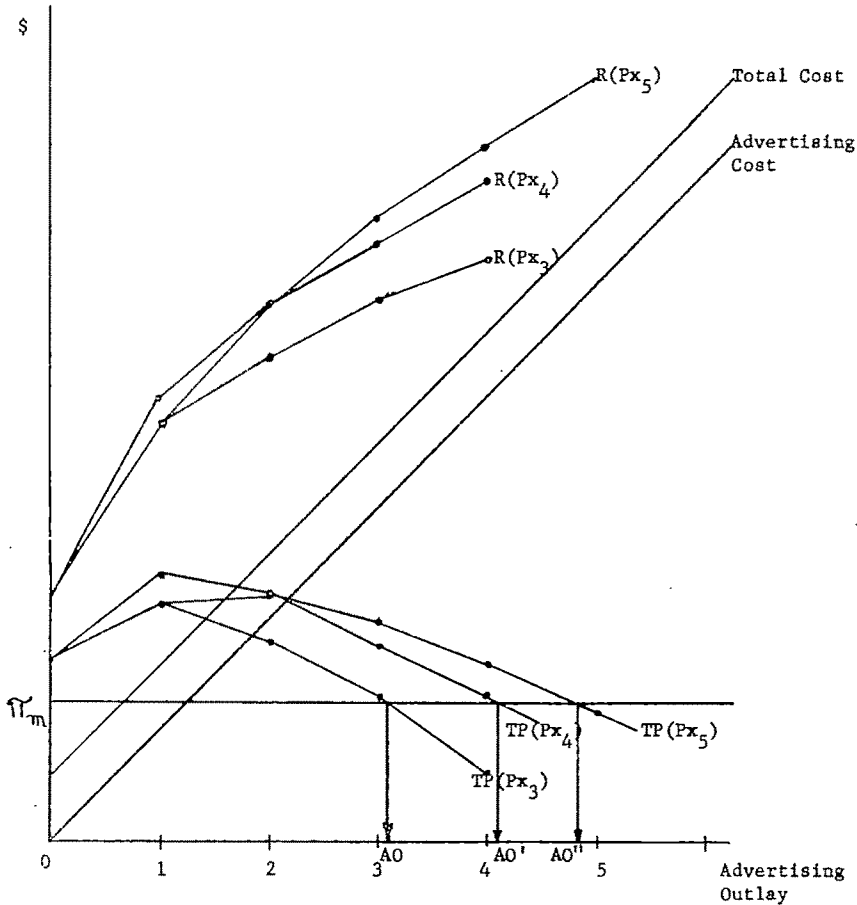

FIGURE 4

increase advertising outlay, which causes output and, given price, sales revenue to increase.

In Figure 4 advertising outlay is measured on the horizontal axis and total revenue on the vertical axis.<sup>4</sup> The revenue functions ( $R$ ) are derived by assuming a given price and then varying advertising outlay; therefore, there is a different  $R$  curve for each of the assumed prices. The advertising and total cost lines are like those Baumol uses. Given total cost, there is a different profit curve for each of the  $R$  curves.

Assuming a minimum profit level of  $\pi_m$ , it is obvious that there are several possible constrained output levels as depicted by advertising outlays of  $AO$ ,

<sup>4</sup>By starting the revenue functions at a positive intercept on the vertical axis, I have circumvented the rather unrealistic assumption, made implicitly by Baumol, that when advertising outlay is zero, output and sales revenue are also zero.

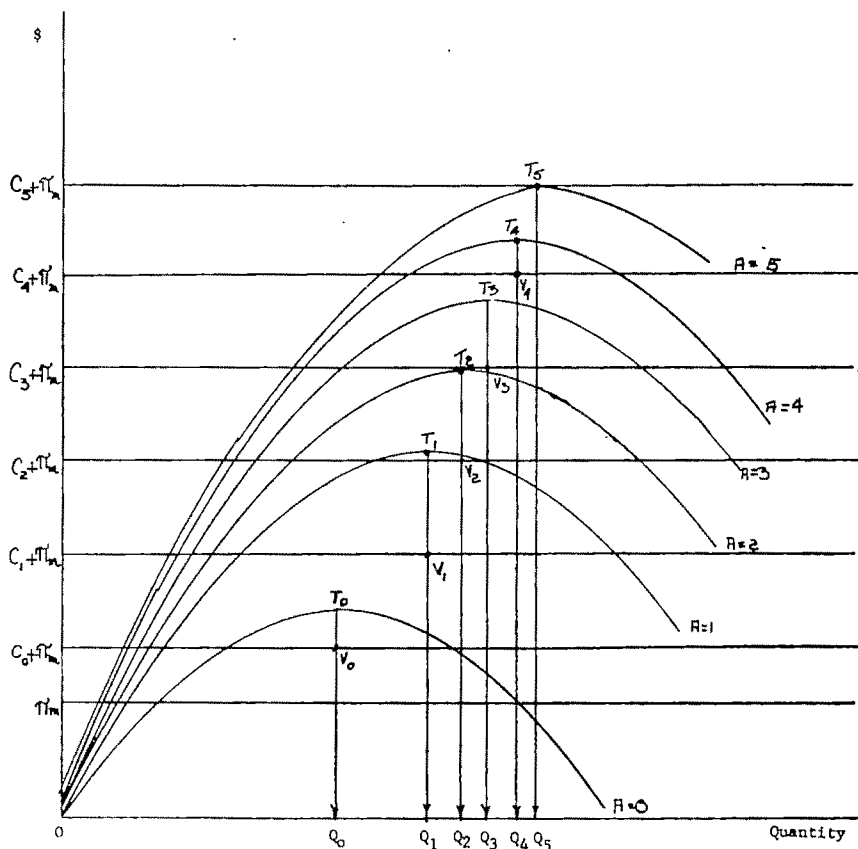

FIGURE 5

$AO'$ , and  $AO''$ .<sup>5</sup> Which of the constrained output levels is equilibrium? This model does not correctly show the constrained output equilibrium. In order to derive the constrained output equilibrium, we must develop a model which allows price, advertising outlay, and product output to change. From this model we will be able to determine the advertising budget and price which determine the output where sales revenue is at a maximum, given the fact that revenue must cover advertising and other costs plus a minimum acceptable profit.

The total revenue functions in Figure 5 correspond to the several demand curves of Figure 3. The firm maximizes sales revenue as long as the revenue covers advertising and other costs plus a minimum acceptable profit. This limitation is depicted by the lines labeled  $C + \pi_m$ . These lines will shift up-

<sup>5</sup> The number of constrained output levels depends upon several factors such as the minimum acceptable profit level, the position of the cost functions relative to the  $R$  functions, and the number and position of the  $R$  functions.

ward at a constant rate once advertising outlay is introduced.<sup>6</sup>

If the advertising outlay is zero and the cost plus minimum profit level is  $C_0 + \pi_m$ , then the firm will be able to maximize revenue by producing output  $Q_0$  at a price of  $Q_0T_0/Q_0$ . The revenue exceeds  $C_0 + \pi_m$  by the amount of  $T_0V_0$ . The firm can increase sales revenue by increasing advertising outlay and price. We now move to the total revenue curve which is the result of one unit of advertising. The cost plus minimum profit level is  $C_1 + \pi_m$ . The firm can maximize revenue by producing an output of  $Q_1$  at a price of  $Q_1T_1/Q_1$ . At output  $Q_1$  revenue exceeds  $C_1 + \pi_m$  by  $T_1V_1$ . Since profits are still in excess of the minimum required, the firm will once again increase advertising and price. With an advertising outlay of two units, the oligopolist maximizes sales revenue at  $Q_2$ , price is  $Q_2T_2/Q_2$ . Revenue is in excess of  $C_2 + \pi_m$  by an amount of  $T_2V_2$ , which means that advertising outlay and price will once again be increased. The oligopolist continues to increase his advertising budget and price until a maximum revenue is attained which is just equal to total cost (advertising and other) plus the minimum acceptable profit. In our model this happens at an output level of  $Q_5$  with a price of  $Q_5T_5/Q_5$  and an advertising outlay of five units. Therefore,  $Q_5$  is the constrained output equilibrium.<sup>7</sup>

One can now use a model similar to Baumol's (which is depicted by my Figure 2) without the confusion which exists in his exposition. The  $R$  function in Figure 6 is not drawn with the assumption of a given price. A revenue of  $R_1$  is attained with an advertising outlay of one unit, an output of  $Q_1$  (Figure 5), and a price of  $Q_1T_1/Q_1$ . Likewise a revenue of  $R_2$  is brought about by an advertising outlay of two units, an output of  $Q_2$  (Figure 5), and a price of  $Q_2T_2/Q_2$ , and so on until the revenue  $R_5$  is reached which is the maximum, given the fact that it has to cover advertising and other costs plus the minimum acceptable profit.

Contrary to received doctrine, Baumol makes the point initially that the large firm (oligopolist) does have an independent and definite price policy [1, pp. 27-32]. He then develops his sales maximization model, which is reproduced in my Figure 1. In this model the firm varies price so as to bring sales revenue to the maximum level unless constrained from doing so by the minimum acceptable profit level. Baumol then abandons his assumption of a definite price policy in favor of changing advertising budgets to describe the constrained output equilibrium; however, he does not tell us how the price is reached which brings about, along with a given advertising budget, this constrained output equilibrium. Once the constrained output equilibrium is achieved, he returns to the assumption that the firm has a definite price policy. For example, in criticizing Professor Galbraith's oligopoly model he says, "To Professor Galbraith, as to many investigators, a prime character-

<sup>6</sup>This is consistent with Baumol's assumption that the advertising cost function is a 45° line and that total cost is parallel to advertising cost.

<sup>7</sup>From the mathematical calculations on which this model is based, the equilibrium advertising outlay is 4.94948974 rather than five. This means that the equilibrium constrained output is slightly less than  $Q_5$ .

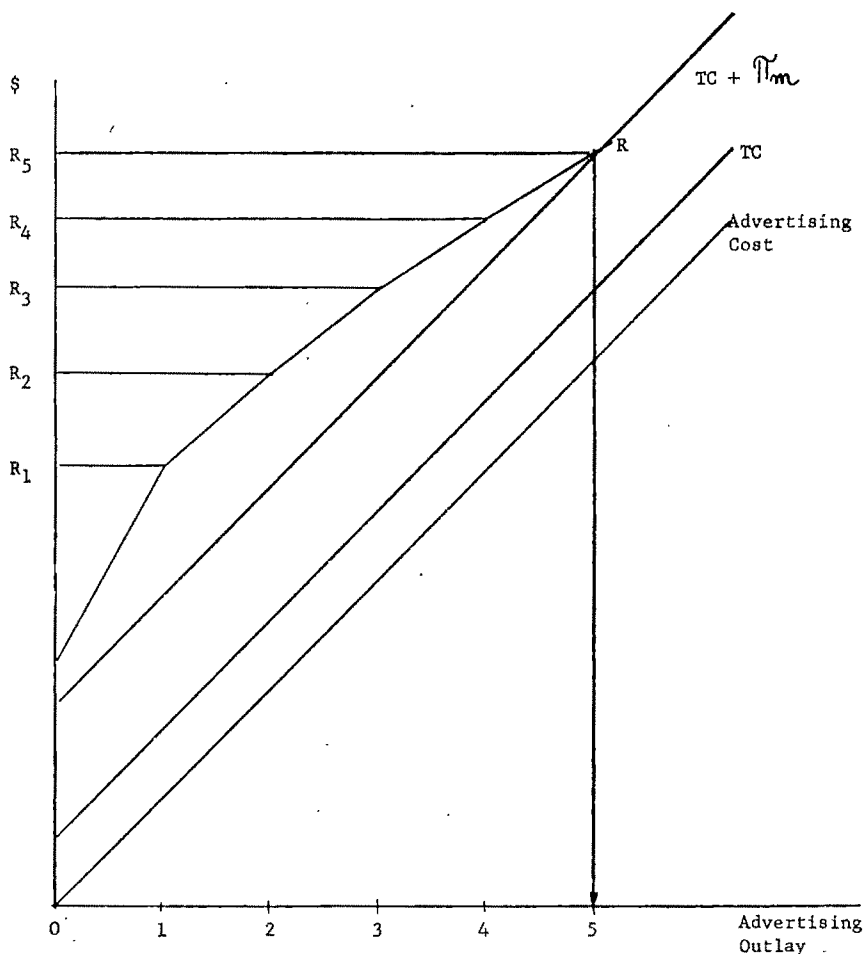

FIGURE 6

istic of the oligopolistic firm is that it does not normally set a price which maximizes profits. So far I am in agreement. But in his analysis there seems to be no alternative explanation of the price setting process" [1 p. 79]. This statement implies that Baumol has explained the price-setting process, along with determination of the advertising budget, which, as has been demonstrated in this paper, is not the case.

### Baumol's Sales-Maximization Model: Reply

Professor Sandmeyer has done a fine job of graphsmanship and shown ably how price and advertising outlay are to be determined simultaneously in my sales-maximization model. It is only to be regretted that he feels it necessary to allege that I failed to recognize the very obvious mutual interdependence of the firm's price and advertising decisions. He takes such a position despite the fact that this interdependence is treated in detail at several points in the chapter of my book at which he directs his criticisms.<sup>1</sup> I had thought that by now a partial analysis is at least an accepted and permissible expository simplification.

Sandmeyer should recognize that, in order for a writer to produce something which is original and correct, it is not absolutely necessary that his predecessors have been wrong.

### General Economics; Methodology

*Strategy and Conscience.* By ANATOL RAPOPORT. New York: Harper and Row, 1964. Pp. xxvii, 323. \$6.95.

Lincoln Steffens tells how he started a "crime wave" by filing stories while the rest of the reporters played pinochle at police headquarters. His competition broke up the game, and for several weeks the harried reporters barraged their papers with exaggerated coverage. Teddy Roosevelt had to go to New York to get the pinochle game going again and stop the crime wave, which was embarrassing the New York Crime Commission. About four years ago a wave of game theory arose, possibly at the RAND Corporation, engulfed the universities, and is lapping at the Pentagon. Even a few members of peace movements have been caught in the undertow. The wave has been tracked by James Newman, Wayland Young, P. M. S. Blackett, and dozens of others who either don't like strategy or don't like someone else's strategy.

Rapoport's is not the first full-length book to sound the alarm, but it ought to be the most authoritative. He is himself a game theorist and a creative scholar (whose contributions to economic theory were unfortunately buried for years in the *Bulletin of Mathematical Biophysics*). His book is a passionate warning to disregard the "strategists," the "cool young men," the "paper warriors" whose thinking is "psychopathic" and "utterly devoid of moral sense," who view "global conflict as a game" and consider "successful nuclear surprise" as a "winning move of a game," who decry the "illusion" that war is a dirty business and invoke the scientific outlook "in combatting the fear and the abhorrence of war." In the expressive language of Karl Deutsch's introduction, the book is "a protest against a glib and shallow fashion of contemporary thought that embodies and enhances man's inhumanity to man." In short, "When I say 'strategist,'" says Rapoport somewhat anti-climactically, "I mean someone who at the moment conceives international problems in strategic terms" (p. 176).

The book makes two points. (1) Strategic thinking is bad. (2) Game theory is to blame. Contemporary strategists express their theories in abstract and mathematical terms and assume that their problems have "solutions"; they "optimize" a "mix" to maximize expected utility, treat nations as "players" motivated by "payoffs," take "rationality" for granted, and "live in a world similar to that of a detective story, where murder is a game of reversed blind man's buff and everyone can be It." They also have an obsession with "gaming" which, Rapoport is occasionally aware, has little to do with game theory except for being equally cute and equally subject to abuse. Furthermore—and Rapoport might have emphasized this more explicitly—their game theory is *bad* game theory if he describes it correctly, dominated by a zero-sum tradition and by "games against nature," so that even in the

most conspicuously adaptive processes the adversary is rigidly assumed to be rigid in his antagonism. (Actually I was surprised that he wrote his book against game theory, rather than one against bad game theory calling for better. By any definition that Rapoport could possibly have in mind, he and Kenneth Boulding are game theorists who explicitly use game theory in elucidating foreign policy, and use it more than any "strategist" that I know of or that Rapoport knows of. So there must be "good game theory.")

Like his *Fights, Games and Debates*, this book is in three parts, and again the third is his personal exploration of what is at issue between East and West, what the capitalist and communist systems have in common and how they differ, what the prospects are for reconciliation, and what kind of dialogue is required for reconciliation. Its only relation to the first two-thirds of the book is contrast: this is a domain that strategists never explore. But since Rapoport acknowledges that hardly anyone does, that is not a characteristic of strategists.

The first third is a technical introduction to probability, zero-sum games, prisoner's dilemma games, and bargaining theory, reminiscent of the first two parts of his earlier book. It is the middle section that tells his thesis, describing what the strategists do and how they think and how they do not think, what is wrong about it, and why it all flows from their preoccupation with probabilities, utilities, and game theory as introduced in Part I. The 75 pages of game theory at the beginning of the book are evidence that I do not misconstrue the author: Rapoport is not saying that the strategists *remind* him of second-rate game theorists and share their style, but that they *are* second-rate game theorists, and this accounts for their analytical style and their foreign-policy premises.

Being one of the accused, I naturally do not care for the first hypothesis, that "strategic thinking" is bad and corrupts the people who rely on it; nor am I impressed with the second, that it all flows from game theory. The first is the one that matters, but is bound to be somewhat impressionistic and likely influenced by the policies one finds congenial. Since we do have this crime wave, and this is a review of Rapoport's book, let me try to dispose of the second hypothesis, which ought to be susceptible to evidence. First, although Deutsch in the introduction says, "The strategic thinkers whom Rapoport criticizes are clearly identifiable from his text," and Rapoport himself says, at one point, "I have now identified the strategists" (p. 186), it is a little hard to tell if he knows *whom* he is talking about even if he knows what he is talking about. The names of seven strategists occur in the book (Herman Kahn, Kaufmann, Kissinger, Knorr, R. Osgood, Schelling, G. Snyder), and they account for 12 items out of 132 in the bibliography. This is my census; they are never listed as a group, nor is the method of selection described. (I am excluding Liddell-Hart, who was a dean among strategists before *Theory of Games* ever appeared; Yarmolinsky, who is represented only by part of a speech he gave; and the Raytheon Corporation, whose mode of thinking is a little hard to personify.) Seven is a small sample, but it probably contains about half of the strategists in print who can be persuasively associated with game theory. Of the seven, four I know personally to be innocent of

game theory; and even if one thinks that William Kaufmann was implicitly infected with it during his sojourn at the RAND Corporation, it is worth noticing that the three selections attributed to him were written ten years ago, before he ever joined RAND. Kissinger has a colleague who would have to plead guilty; but even guilt by association would have to be retroactive for the work cited by Rapoport, since Kissinger wrote it before I ever met him. It boils down to three possible game theorists, against one of whom the evidence is that he included six simple matrices and one probability equation in an otherwise "literary" book on defense policy; and I can certify that his analytical style in that book is the same as in things he published before he adopted matrices for his bookkeeping. That leaves two, Herman Kahn and myself. (I hope that both Kahn and the game theorists will let me include both of us here for the sake of argument.)

Whatever else one may say of the two of us, we are bound to defy statistical analysis. Anyone who has met Kahn will surely acknowledge that he cannot be described as a man so ordinary in all other respects that his passing interest in game theory and the style of his strategic analysis have an indubitable relation of cause and effect. David Riesman once hinted that civilian strategists act tough because, not knowing at first hand the cost of war, they need to prove themselves virile. As a conjectural diagnosis, this must compete with Rapoport's. I know two outstanding strategists within the Department of Defense who are devout Catholics but, then, there are Jews among us and at least one Olympic skier, and I don't know what else. Neither does Rapoport. So his correlation coefficient relating game theory to "strategic thinking" is suspect; but it is too low to be interesting anyhow, just two out of seven in his sample.

I can raise the absolute number by adding Oscar Morgenstern, whose *Question of National Defense* is unaccountably missing from Rapoport's bibliography, and Daniel Ellsberg, as well as one or two others who might be identified both with strategic thinking and with game theory, but in a larger sample the denominator would rise at least proportionately. (The exclusion of Wohlstetter goes against recent tradition, but Rapoport treats the strategists as sufficiently interchangeable for it not to matter.) And I would have to put Rapoport himself and Boulding and a few other good guys into the sample, and I am not sure the correlation of monstrosity (his word) with game theory even comes out positive. One can also raise the question whether foreign relations is uniquely the field in which game theory leads one astray. Rapoport admires Braithwaite for his "charming and perceptive book," *Theory of Games as a Tool for the Moral Philosopher*. Karl Deutsch, who likes this book enough to introduce it, also likes game theory applied to politics and says so in his *Nerves of Government* (1963), but is uneasy about its relevance to foreign affairs. There is thus a hint that game theory stultifies only those who worry about Russians. If so, it calls for a more refined psychological analysis.

I have read one other full-length manuscript devoted to the thesis that game theory—literally game theory, the kind that got started with von Neumann and Morgenstern—accounts for the depraved quality of American stra-

tegic thinking, and one in print (Irving Louis Horowitz, *The War Game*) that, though it confuses game theory and "gaming," makes much the same point. Since statistical analysis of the open literature cannot possibly support the proposition, I wondered whether there was a reasonable premise that could make it true. There is: these few gamely theoretical strategists occupy but the top of an iceberg. They are emigrants from classified organizations whose analytical style they typify; behind them is a vast population of economists and game-theory strategists who not only dominate policy but impose their fashion on the nongame-theory publicists. This would be a reasonable conjecture, but being reasonable doesn't make it right. I have been submerged, and I did not see the iceberg underneath. No one has to take my word for it; still, an author might just ask somebody, and there is no sign that these authors did.

In fact, though Rapoport remarks on "the paucity of psychological knowledge among strategic thinkers" and says there is little evidence "that either the empirical findings or the insights of social scientists find important application in strategic thinking," and though Deutsch in his introduction agrees that the ignorance of psychology among the strategists is "appalling," I am not quite ready to accept Rapoport's book as a model of empirical research, even if he is permanently associated with the Mental Health Research Institute of the University of Michigan. He asserts that the "strategists are also exactly like other people of their social class, education, and background," but cites no evidence and does not indicate how he drew his sample or even if the seven named are his sample; he names some philosophers and novelists he is sure they do not read and some books they do not like (pp. 170-71), but did not ask them; he adverts to "decisive evidence" in their preoccupation with gaming, a preoccupation of which there is no hint in the cited works of four of his seven, but about which it would have been easy to inquire; he hints at a lack of combat experience but gives no indication he checked war records or draft status; and of course he has written a whole book about their thought processes and what motivates them. No wonder Karl Deutsch hedges his introduction by saying, "He [Rapoport] admits freely that he sometimes has overstated his points in order to ensure them attention." (Incidentally, I read the whole book and noticed no such admission.) I am reminded of Horowitz, who devoted an entire chapter of his book to the question of whether the NCMs ("New Civilian Militarists") should be embargoed or talked to, and came out favoring the strongest possible contact of right-thinking people with the strategists, but who, in writing his book about the habits and views of several strategists whom he identified by name, never once got in touch with them by phone, mail, or interview (and in consequence not only confused their policies but got several of their names wrong). Rapoport cannot be charged with such inconsistency, since he explicitly doubts that it is "worthwhile to try to bridge the chasm between strategic and conscience-inspired thinking." He considers it "imperative to establish avenues of communication between Blacks and Whites, and between East and West, because they all must either learn to live with each other or perish." But "in the case of strategy and conscience," he says,

"I am not sure. Here, I believe, is essential incompatibility, not merely a result of misunderstanding" (p. 195). It is no wonder that he knows so few of them and so little about them.

Since the book is about a style of thought and not policy, it is not surprising that he rarely identifies the bad policies that strategic thinking leads to. There might even be a hope that the wrong thinking would lead to the right answer, and the strategists would be harmless. There is one main policy orientation that he attributes to the strategists, and on this he is correct. They all take seriously the role of military force in deterring military action by foreign countries. They may not take it more seriously than most policy-oriented Americans, but among intellectuals their concentration on the military side of foreign policy is rivaled only by that of the peace movements. But as "policy" this is not very specific. The only specific issue that gets Rapoport's attention is civil defense, and on this I might hazard a little psychology of my own, after the fashion of Rapoport.

First I note that of the seven strategists represented, only four have published anything on civil defense, with the exception of Kissinger who implicitly disparaged it in the book cited. Snyder devoted a few unemotional pages to it in his book and Knorr wrote a chapter on the subject nine years ago that was cautiously favorable to taking the subject seriously. Rapoport seems to think (pp. 86-87, 94-95) that his strategists are civil-defense enthusiasts and in particular that they do not recognize the "provocative" aspect of civil defense or the feedback effect on the arms race. I believe—and this is just taking my turn at amateur psychology—that Rapoport is still twitching from the shock of Herman Kahn's book and supposes that Kahn represents the RAND Corporation, the Air Force, Princeton, Harvard, game theory, and the Kennedy Administration. (He says that "Kahn became the loudest and clearest spokesman of the 'cool young men.' " It saves reading a lot of strategy if you can rely on that.) Actually, the only game theorist I know who in print considers "defenses" innocuous is Kenneth Boulding (*Conflict and Defense*, 1962), who cannot possibly be accused of the sins of the strategists. Boulding said, "Thus, a shield, a city wall, or a bomb shelter are purely defensive armaments: they lessen the capacity of the enemy to harm but can in no way harm him" (pp. 258-59). This was just a slip on Boulding's part, but a slip I believe would not occur with Rapoport's "strategists," who typically *insist* on the interaction of civil defense with enemy responses, not neglect it. In two of the works attributed to Schelling, the implicit and explicit treatment of civil defense is exclusively concerned with the "feedback." And what aroused many people was not Kahn's treating civil defense as innocuous "insurance" but his advocacy of its "provocative" merits; it is easy to disagree with him, but not on grounds that he was silent on the very point one disagrees with!

Actually Rapoport is not quite as wrong about the strategists as I make him sound, even though his evidence is disgraceful, and all he has is a hunch based on a small biased sample. The game-theory hypothesis was not a bad guess, but a wrong one. The research technique is a bad example. There is no treatment of issues, just thought processes. There is occasional misrepre-

sentation of policies, but on the whole so little about policy that it does not matter. And there is a slightly insulting effort to cast a diverse and ill-defined group of individuals as a single type. Nevertheless, there *is* a contemporary style of thought and analysis that deserves to be characterized as "strategic thinking," and whether it is good or bad, it may deserve to be studied. It has been studied, but not by Rapoport. Robert Levine's book, *The Arms Debate* (1963), contains an excellent analysis, not of strategists but of how they reason in print. It misses the point, according to Philip Green (*World Politics*, July 1964), for not being *ad hominem* and thus neglecting some key moral issues, and according to Marcus Raskin (*The New York Review of Books*, Nov. 14, 1963) for not being *ad hominem* and thus neglecting the payroll that determines a man's point of view. What it does, though, it does well. But psychiatric examination of amenable, locally available, live subjects that confines itself to a man's published work, and not all of that, seems to me a lazy clinical practice.

The word "conscience" in the title has an important meaning for Rapoport and arises in his own interest in game theory. He has been fascinated, like many of us, with the situations characterized as "prisoner's dilemma"—the situations in which individual "rational" decisions produce inefficient outcomes. These are the situations in which "cooperative" choices by two participants could make both better off, but neither has incentive to choose "cooperatively," even if the other does. Rapoport is annoyed that a "solution" based on "rational choice" should be inefficient and wants to redefine rationality so that it is collectively rational to make cooperative choices even though individual incentives go the other way. Under a test ban without inspection, he pointed out some years ago, a country may be better off cheating if the other cheats and better off cheating if the other does not, but in the end worse off with both cheating than if both abstained. Conscience—a sense of honesty or obligation—could lead each party to eschew his individual interest with the happy result that virtue brought its own reward. (Less reward than if one cheated against a virtuous partner, but nevertheless a joint reward compared with joint cheating.)

It is hard to tell whether or not he really has an argument with those who call the noncooperative and unhappy outcome the "rational solution." I prefer to emphasize that there *are* situations in which individual rationality leads to inefficient outcomes and in which there is no sense of obligation to bring about cooperation; I prefer it because recognizing such situations raises a universal and massively important problem of social structure. Rousseau's *Social Contract* is an illustration of the need to structure obligations—through conscience if one can create conscience, otherwise through damage suits, hostages, bail, inspection schemes, synchronization of choices, or anything else—to eliminate the subversive incentives, changing the payoffs or adding new strategies. Conscience is great if it will do the trick; and it must account for an enormous amount of efficiency in social and economic arrangements where the purely material incentives could be quite disruptive. It may even explain why people vote on election day. Like Voltaire, who preferred God-fearing servants, we can attach great utilitarian value to the

implicit sense of social contract—of honesty, decency, and identification with each other—that we are brought up with. (This is in addition to the attractiveness of conscience and honesty as human qualities, but an important addition.)

Rapoport wants to derive a justification for conscience out of game theory itself, making conscience a universal part of the solution to games of the prisoner-dilemma type. As a theorist I disagree with the apotheosis of conscience; there are too many cases in which society depends on inefficient results. The Mafia have solved the prisoner's dilemma efficiently and are the better terrorists for it, as did the Secret Army Organization in Algeria, and so do the purveyor of mail-order pornography and his juvenile customers who have a serious problem of "trust" to surmount. The social value of efficiency, or its esthetic attraction, depends on who is being efficient about what.

Rapoport might agree with me as a theorist but, on matters of war and peace, he does not believe in disinterested research. He sees experimental probings as "actions which *in themselves* can induce a reorientation in thinking about international relations, that is, actions which bring about changes in the political climate." He is interested in the impact that "research *as a social activity* can have on the society which supports it" (italics his, pp 173, 174). If we start asking different questions, he says, we become different people. This explains his preference for a new definition of "rationality," one that is collective rather than individual, conscientious rather than strategic, and his strong belief that strategic thinking is bad no matter how good it is. Seduction lurks, he says, in the mental habit of rational analysis, "for this analysis requires detachment," and detachment leads one "to ignore human characteristics when dealing with human beings" (p. 109).

For sheer stimulation there are few social scientists whose work I have found more rewarding than Rapoport's. For that reason my disappointment in the present book is the more poignant. I am not a disinterested reviewer.

*The Nation's Economic Objectives.* Edited by EDGAR O. EDWARDS. Chicago: University of Chicago Press, 1964. Pp. ix, 167. \$4.95.

On the occasion of its fiftieth anniversary, in 1962-63, Rice University presented a series of public lectures on national economic issues by eight distinguished economists. *The Nation's Economic Objectives* is based on these lectures. Rice University and Edgar O. Edwards, editor of the volume, deserve congratulations for offering articles, not previously published, by these authors on these subjects:

Kenneth Boulding	The Dimensions of Economic Freedom
Arthur F. Burns	Economics and our Public Policy of Full Employment
Lester V. Chandler	Economic Stability
Seymour E. Harris	U. S. Welfare Programs and Policies
Simon Kuznets	Notes on the Pattern of U. S. Economic Growth

Fritz Machlup	International Economic Cooperation
Edward S. Mason	Objectives of a Mature Society
Jacob Viner	The United States as a "Welfare State"

This book will be a source of pride and pleasure to economists. We can be proud of the demonstration that some economists have something important to say to the public and can say it in an understandable and interesting way. We can enjoy the pleasure of meeting distinguished scholars, and in some cases old friends, almost face-to-face. The styles and personalities of the authors come through in these essays with amazing fidelity.

Of course, one can wish that some things were different. To devote only one of eight essays (or one-fifth of the total pages) to international questions seems to me unbalanced in today's world. Fritz Machlup's essay on international economic cooperation is a model of how much information, classification, and analysis can be compressed in 33 pages. He makes the significant and, to me, novel observation that international economic cooperation, so generally regarded as a "good" thing, has been throughout history an instrument of protection and exclusion, and is still so today to a considerable degree. Nevertheless, the volume would have benefited from more pages on our economic objectives in relation to the rest of the world, even if this had required omitting some of the pages on other subjects now included. Also, one wishes that Arthur Burns's talent and experience had been directed to a more fruitful subject than whether or not our national objective is zero unemployment, and that Seymour Harris had left his shower of statistics behind and given us his mature reflections on welfare programs. Still, what is here is well worth the price of admission.

Since space is too limited for comment on the eight essays singly, I hope that the reader will pardon the special interest of a former student in Professor Viner's essay on "The United States as a 'Welfare State.'" This is genuine Viner—urbane, sharp, and energetic. It contains this blockbuster of a sentence:

If, therefore, I nevertheless conclude that the welfare state, like Old Siwash, is really worth fighting for and even dying for as compared to any rival system, it is because, despite its imperfections in theory and practice, in the aggregate it provides more promise of preserving and enlarging human freedoms, temporal prosperity, the extinction of mass misery, and the dignity of man and his moral improvement than any other social system which has previously prevailed, which prevails elsewhere today, or which, outside utopia, the mind of man has been able to provide a blueprint for.

Some of our new federal office buildings in Washington are big enough to accommodate this inscription in one unbroken line on their lintels. But before this sentence is chiselled on many buildings, Viner's text should be carefully studied. He defines "welfare state" broadly, to include not only all the varieties of combinations of social and economic policies found in non-Communist advanced countries but also almost all the different policies seriously considered in those countries. There is no implication that we have

here in the United States that one state among all possible welfare states that is best for us. There is no suggestion whether we are on the too "welfarish" or the too "unwelfarish" side of the optimum. Thus Viner leaves ample room for the policy debate that is the bread and butter of economic discussion. What he excludes is the aggrandizement of that debate into a conflict among rival systems.

The prevailing mood of the eight essays is satisfaction. The authors do identify some problems about the U. S. economy, and there are some warnings against complacency. But the problems are not alarming or fundamental—the urban traffic problem is probably a typical example—and the warnings against complacency are required only because the general argument tends towards complacency. The theme of the volume may be in Viner's striking quotation from Robert Frost:

... How are we to write  
the Russian novel in America  
As long as life goes on so unterribly?  
[New Hampshire (1923)]

Certainly these eight professors of the dismal science have not written the Russian novel about the American economy.

I share this contented view, and yet I worry about it. Note that the quotation is from New Hampshire, not from Harlem or from Mississippi, and that the year was 1923, the year before James Baldwin was born. Perhaps the Russian novel is still to be written here. These papers give little hint of the concern, or crisis, about the related problems of poverty and race in America that was already boiling up when the lectures were delivered. Neither do they give much hint of America's possible involvement in the problems of poverty and race that exist in the "outside world." Probably it did not fall within the special competence or assignment of any one of the authors to supply this, but the reader should be aware that something may be missing.

*Committee for Economic Development*

*Political Economy*. Vol. 1, *General Problems*. By OSKAR LANGE. Translated from Polish by H. H. Walker. Oxford: Pergamon Press; Macmillan, distributor, 1963. Pp. xiv, 355. \$6.50.

This volume of Professor Lange's most recent major work first appeared in Polish in 1959 (it met with instant success) and has already been translated into French and Italian. It is the first installment of a three-volume work that attempts, in the light of the Marxian conception of political economy, to synthesize the author's studies in the various fields of economics. The seven chapters deal with general problems of political economy and fall into four parts. First, a philosophical part discusses the subject matter of political economy, the connection between political economy and the materialistic interpretation of history, and the economic laws. The second part is methodological, the third deals with application and economic prediction, and the last is a critical evaluation of non-Marxian trends in political econ-

omy. The next volume will be "a critical exposition of the most fundamental problems of political economy" (the theory of reproduction and accumulation, market production and the law of value). The third volume will be devoted to "a detailed analysis of the mode of operations and the 'law of motion' of the capitalist and socialist formations."

The volume under review discloses the *alter ego* of Professor Lange: the missionary. The author had at long last Truth revealed to him, and he intends to break the news to the world. Sample section headings from the last chapter: "Full development of political economy is only possible in connection with the labor movement" (p. 319); "Only the working class is interested in full scientific knowledge of economic laws" (p. 344); "Union with scientific socialism is the indispensable basis of the further development of economic science" (p. 340).

A by-product of having known truth is the discovery of the "true social welfare function." The principle of economic rationality under capitalism is subject to the private ownership of the means of production and thus involves only maximization of private profit and operates antagonistically (p. 173). The result is social diseconomies, waste of productive resources, unemployment, economic crises, etc. On the other hand, the social ownership of the means of production and the development of *social* economic rationality guarantee under socialism the maximization from the point of view of the economy as a whole.

The integration of the aims of the activity of socialist enterprises by a common end established in the social economic plan leads to a hierarchic structure of ends. . . . A hierarchic structure of ends is a peculiarity of the socialist mode of production just as a peculiarity of the capitalist mode of production is the existence of independent parallel aims of individual enterprises: their attempts to obtain the maximization of their profits. For the hierarchic structure of ends is the expression of the social economic plan and the integration of the aims of individual socialist enterprises by a chief end laid down in the social economic plan. It is at the same time the expression of the social rationality of the socialist mode of production (pp. 179-80).

Where does this leave us in terms of the discussion that Lange started with von Mises more than 25 years ago?<sup>1</sup> He then thought that to solve the economic problem three data are needed: (a) a preference scale which guides the acts of choice, (b) knowledge of the "terms on which alternatives are offered," and (c) knowledge of the amount of resources available. His preoccupation then was with (b), and he proceeded to show that the formal resource allocation is similar under both capitalism and socialism. If all conditions were satisfied, profit maximization under capitalism would have been *utility maximization*. Since all conditions are not satisfied, however, capitalism may proceed by adding, in the Pigovian way, some rules to internalize certain costs—be it progressive taxation, nationalization, fair trade commissions, etc. Lange then saw a case for socialism only on the basis of the

<sup>1</sup> Oskar Lange and Fred M. Taylor, *On the Economic Theory of Socialism*, (B. E. Lippincott, ed.), Minneapolis 1938.

*actual* resource allocation. Capitalism could certainly handle externalities by adding some constraints and equations to the system. Only socialism could do that directly. Or, as Dickinson put it, "socialism would work, as it were, in a glass house, in which all the details of its mechanism could be followed."

All this is past history. Today Lange not only has second thoughts on capitalism's knowledge of the alternative cost of resources, but he also has changed his mind about the nature of the objective function. He actually substitutes the holistic for the private welfare function.<sup>2</sup> Socialism maximizes a function that (by revelation) embodies the thinking of the whole or the Hegelian "collective spirit."

The rest should come as no surprise to the reader. Capitalism is matched to the "true" yardstick and flunks the test. We can present here only a few of the crimes that have been committed in the process.

A suitable (mis)interpretation of rationality helps if one is to show "the limited and socially warped character of private capitalist rationality" (p. 264). The conclusion could have been easily avoided if one interpreted rationality as consistent choice or transitivity of preferences rather than connecting it with deliberation or reflection. In the former sense rationality is a necessary and sufficient condition for maximization in economic activity, and it applies not only to the business world (as Lange admits) but also to household activity (which he denies). Thus, Lange holds capitalism responsible for the "derationalization" of household activity in the sense that consumers are cajoled to buy on impulse, habit, emulation, etc.

After Marx, Lange's economic laws are apocalyptical and thus are "verified" rather than confirmed or rejected (pp. 125 ff.). They are also supposed to be objective and independent from human will and consciousness. To this reviewer they appear to be dependent on the conditions of substitution between factors of production ("technical laws of production," i.e., the technical production coefficients), meaningless truisms ("balance laws of production," e.g., "no more coal can be used than can be produced plus or minus imports or exports"), or hypotheses with missing or confused necessary and sufficient conditions ("laws of interplay of human actions," e.g., the law of the disappearance of surplus profit).

The results of the capitalism-socialism matching game, although predictable, are not without interest. Some sample quotations will illustrate: "The methods of social accounting especially input-output analysis find their full application . . . only within the framework of the socialist mode of production" (p. 186); economic crises "are the result of the limited, private character and antagonistic operation of the principle of economic rationality when applied in capitalist enterprise" (p. 176); "A considerable proportion of our knowledge of programming is not used in capitalist enterprises or capitalist states because its application demands a coordination of the activities of individual enterprises, which is only possible when the means of production are socially owned" (p. 204). It is one thing to state that capitalism cannot do the job and quite another to say that at the present state it does not.

<sup>2</sup> K. R. Popper, *The Poverty of Historicism*, London 1957, pp. 76 ff.

A few concluding remarks should not be read just as perfunctory pronouncement of professional niceties. The book is certainly worth reading, notwithstanding the fact that this reviewer devoted his space to volleying at the author. The philosophical part presents a nice elaboration of Marx's ideal types. The discussion of political economy and praxiology, of marginal calculus, of programming, and a short appendix on its mathematical foundations still allow the reader a distant glimpse of the author of *Econometrics*. The attempt to write a political economy of socialism alone, given the present state of the art, is certainly a contribution. One suspects that the best is still to come in the next two volumes.

*A Strategy of Decision—Policy Evaluation as a Social Process.* By DAVID BRAYBROOKE AND CHARLES E. LINDBLOM. New York: Free Press of Glencoe; London: Collier Macmillan, Ltd., 1963. Pp. ix, 268. \$5.95.

This is a book meant for "analysts" whose task consists of the evaluation of measures of economic policy. It recommends a "strategy" standing at variance with what the authors call "synoptic" methods, the best of which are characterized by the use of a social welfare function which is to be maximized. They charge that the latter method is impracticable and that a social welfare function has never been constructed. The method they defend is called "the strategy" or the method of "disjointed incrementalism." It consists of an evaluation of some alternative policies, usually covering only a portion of "total" policy—hence "disjointed"—and aiming at relatively small changes of the total order—hence "incrementalism." For their strategy they claim that it simplifies the analysts' task, first of all through "omission," that is, by not considering all conceivable alternatives, but only a few feasible ones; then, because it only uses the restricted knowledge available and capabilities of the people in charge of the work, no "supermen" are needed. It considers only such policies as are attractive also from the "means" side; the desired simplification also materializes through "fragmentation" by "serial" and "remedial" steps or "reconstructive features." Under the heading "omission," as a simplifying feature they also mention the possible omission of even "important consequences" of the policy measure to be analyzed. They justify it by a possible later remedial step, making up for the forgotten consequences; in the reviewer's vocabulary this is an example of the good old "trial and error" method. They describe their strategy as "meliorative" rather than "peremptory" and also characterize it as "openminded" and "flexible." Finally they feel that the strategy contributes to the solution of some ethical problems.

The reviewer's impression is that the authors are well versed in practical and detailed policy evaluation, and they rightly emphasize that in such work perfectionism is a bad thing. They are fair and modest in their claims, and many features of their "strategy" are typical for much project evaluation in development planning. In their zeal to defend their attitude they introduce lots of terms (several of them to be found in the previous paragraph of this

review in quotes). To the reviewer several of these features look like duplications; is "fragmentation" very different from "disjointed," "serial" from "incremental," "openminded" from "flexible," or is not openmindedness a feature of the analyst rather than of the strategy? The word strategy appears somewhat ambitious, by the way, in the light of the present-day, very precise meaning of this term in more perfectionistic procedures.

The reviewer also wonders whether the controversy created by the authors is somewhat imaginary in that the "synoptic" method is used for a different type of problem, mainly for the macro-stage in policy planning, where some of the main interdependencies in the economy are at stake, or for welfare-economic propositions of a very general character, meant to find the basic features of the optimal order. For the macro-stage it is characteristic that the various means or instruments used can be combined in many different ways, whereas in projects or single policy measures or schemes the means often are complementary, and the combination can be taken or left. The authors are aware that they do not always go on until the maximum of welfare has been reached, but only take a step in the right direction. This is true also for the use of a set of given projects in a development policy, but it may actually be a wrong policy, to the extent, for instance, that some good project could be carried out several times. In other words, the quantity of such projects should be considered to be unknown—a feature of mathematical programming which makes this technique really superior to that of project selection with each project considered as an individual and unique "possibility."

The reviewer is somewhat puzzled by what the authors may have in mind when they claim a contribution to the solution of ethical problems. Not being an expert on ethics, he may be wrong, but he feels that neither ethics as it is nor this book helps the economist much in solving ethical problem number one for welfare economics, namely the comparison of utilities of different persons. Here they simply remain on the unsatisfactory, agnostic level of judgment still *en vogue* in present-day economics and leave all the ethics to the politicians and the pressure groups.

While the reviewer considers the book a sound presentation of the practice of evaluation (of both policy measures and projects), he feels the authors missed the possibility of building a bridge to the methods they criticize. It is not quite true, by the way, that no social welfare functions have been constructed; Van Eijk, Frisch, Sandee and Theil may be quoted to the contrary. The point is that the synoptic method is the only one for some other classes of problems, already mentioned. The book under review has the merit, however, of reminding the reader or producer of macro-stuff of the innumerable qualitative and quantitative variables playing a role in the micro-phase of policy-making.

*Modern Economics.* By STANLEY P. WRONSKI, FRANCIS S. DOODY AND RICHARD V. CLEMENCE. Boston: Allyn and Bacon, Inc., 1964. Pp. viii, 438. \$4.84.

This book is designed to meet an often-expressed need for a good high school textbook in economics. How well it meets this need is another question. But before proceeding to that question, perhaps it would be pertinent to ask whether what is demanded of such a text is in fact possible. Clearly such a book must do more than duplicate between hard covers the level of economics already available in newspaper editorials and magazine articles. Yet it cannot exceed the capabilities of high school students or—a more severe practical limitation—the level of difficulty which the public schools are prepared to impose on them. But even more important, given the potentially controversial nature of the material and the vigilance of interested groups, how is such a book to carry out the demolition of popular myths and the wholesale slaughter of sacred cows—which real education necessarily entails—and still expect acceptance in the public high schools? Obviously a ‘Cook’s tour of economic miscellany is much easier and safer, and that is what is too often provided. This book is no exception.

Judged for what it is, rather than what it might have been, *Modern Economics* has its merits. It is largely free of explicit moralizing and the bias of implicit value judgments, which have been severely criticized in other high school texts. Its theoretical sections are sufficiently well done that there need be no fear that the student will have to unlearn them in college. Unfortunately, the analytical segments of the book are very small, and no relationship is established between them and the numerous topics discussed. For example, supply-and-demand analysis is introduced early in the book but is totally ignored in later discussions of the farm problem, minimum wage laws, and public utility regulation. Similarly, fixed and variable costs are carefully distinguished, but no use of this distinction is made, even though there is a chapter on international trade which might have mentioned its relevance to dumping, and a chapter on government regulation which could have shown its importance in “natural monopolies.”

While there are many topics, there are few issues. Not only are controversies avoided, the very fact that there are controversies is largely ignored. Even the chapter on the role of government in the economy presents an unruffled surface simply by discussing particular government programs in terms of their avowed purposes and institutional mechanics, rather than in terms of their results or the issues they raise. It can hardly be claimed that this is preparation for informed citizenship.

As so often happens, analytical weakness is accompanied by excessive factual detail: the intricacies of labor arbitration procedures, detailed comparisons of various forms of life insurance, a list of retail prices in the Soviet Union, etc. Numerous photographs are included—no doubt a desirable feature at the high school level—but the particular pictures chosen are mediocre and insipid—as is the text too often. Some captions: “Planned saving made this family vacation possible”; “It is essential that this man study

carefully the insurance policy that he is buying"; "The search for oil is a never-ending venture that takes men to unlikely places."

There has long been a crying need for an intelligent citizen's guide to economic thinking. There still is.

*The Theory of General Economic Equilibrium.* By R. E. KUENNE. Princeton: Princeton University Press, 1963. Pp. xv, 590. \$12.50.

This book affords a rather comprehensive review of the main body of general equilibrium theory from Walras to Arrow-Debreu. The fact that much of the material is presented nearly in the form in which it first appeared lends a historical flavor to the book. There is also a good deal of exegesis of the classics, especially Walras, and some attention to doctrinal controversy, especially in the theories of capital and money. The scope of the work is thus quite ambitious, although Part II, which is over half the book, is parallel in its development to the main chapters of Walras' *Elements*. It is an elaboration of Walras with the help, primarily, of the work of Hicks as presented in *Value and Capital*, but with the help, also, of Wickcell and Fisher on investment and of Lange and Patinkin on money.

The methodological viewpoint of Part II is that clearly put by Hicks and Samuelson, the development of comparative statics from an assumption that the model has certain stability properties. Thus quantitative results are sought, such as the direction of price change when the supply of a good is reduced, when none but very general properties of the model are used. The author asks that the theorems have operational meaning in the sense of Samuelson. Of course, he is led to observe that very few results are forthcoming in a general model. Indeed, this discovery is made many times and tends to produce a feeling of futility, so that one begins to wonder why the author bothered to write his book.

A weak defense of general equilibrium analysis is raised by introducing the value of the "vision" of the economic process which it embodies. I am not clear how this vision is effective, but in any case the author is rather apologetic about this excuse for his enterprise as well. I find his pessimism a bit surprising since it seems clear that nearly all economics nowadays is general equilibrium economics or closely allied to it. Certainly the theories of international trade, of money, of employment, and of economic growth are general equilibrium theories, in however simplified form, and are not thought by most to be entirely useless. Also the modern approach to the theory of planning is an outgrowth of general equilibrium theory. Even the emendation (or rediscovery) of Marshall's partial equilibrium theory by Friedman seems aimed chiefly at putting it in a general equilibrium setting. No doubt the usefulness of these simplified versions of the general model comes

partly from our willingness to introduce numerical quantities for the parameters or at least to hazard orders of magnitude for them. Also, the applied models are macroeconomic, and the Walrasian model is microeconomic, but this should not obscure the dependence of the former on the latter, logically, and often in the development of thought as well.

There is, I think, a major omission from the topics in general equilibrium which are discussed. This is welfare economics or, perhaps better, the theory of Pareto optimality. I think that Walras was groping for a valid optimality theory, just as he sought to prove existence, uniqueness, and stability of equilibrium. He did not succeed, but he should be commended for retaining his abortive efforts, which have now led to a valid theory. The efficiency and optimality interpretations of the price system of competitive equilibrium were brought out clearly in Koopmans' activity analysis, and in Arrow's chapter on welfare economics in the *Second Berkeley Symposium* [1]. Unfortunately, in the present book, the transition from activity analysis to competitive equilibrium and the role of the efficiency prices is not given proper emphasis, and Arrow's contribution is omitted altogether. Of course, there is much talk of shadow prices, but the context is usually linear programming for profit maximization in the firm. The absence of the efficiency interpretation of the price system is severely felt in the treatment of capital theory. The discussion could have been clarified by appealing to the fact that an efficient program of production over time or a Pareto optimal program of production and consumption over time *implies* a price system, intrinsic to the program, from which the interest rates are derivative. I would think this body of theory on the implications of Pareto optimality is at least as important as any other part of general equilibrium theory.

There are a number of inflated passages which may irritate many readers ("The ubiquity of variation, manifest in the very triviality of its assertion, forces upon man, individually and collectively, a concern for its patterns," p. 3). Also some of the word usage is in doubtful taste ("generalness" for "generality" in several places). The mathematical notation does not improve on Walras, and the use of subscripts is sometimes ambiguous. There are quite a number of places where the mathematical argument is treated casually and becomes quite hard to decipher. On the other hand, the practice in Part II of using small-scale systems with three or four independent variables in which to conduct the argument is quite helpful to the reader, and the exposition of Leontief models and of linear programming is often well done.

I will now review the chapters in turn. Chapter 2, "The Exchange Economy," develops the theory of consumer choice according to Slutsky and Hicks and applies it to the theory of exchange in the manner of Walras and Hicks. There is an unrelated section on Morgenstern-von Neumann utility as well. However, no use is made of the revealed-preference or the minimum-income approaches to demand theory [5]. The methods of proof are those of the Hicks appendix to *Value and Capital*. Theorems are derived chiefly from assuming that income effects cancel out or from using Hicks's stability arguments. The author concludes that the stability argument adds nothing. However, this conclusion seems too severe, since it seems to be based on the fact

that what is derivable from the stability assumptions can also be derived from the maximum conditions when income effects cancel. Of course, the two sets of assumptions need not be treated as alternatives. The Hahn-Negishi theorem on systems in which all goods are gross substitutes is applied to derive the Hicks perfect stability conditions. However, the argument is incomplete (p. 127). Cardinal utility is treated as a meaningful concept even in a context of choice with certainty (p. 94). However, I do not see the justification for this in the absence of a theory that assigns a distinguished role to a set of utility functions, invariant under linear transformations.

In Chapter 3, "The Production Economy," this line of reasoning is continued, again in the manner of Walras and Hicks, with, as before, a considerable amount of historical annotation. Successive models of the firm of increasing generality are examined and embedded in successive Walrasian general equilibrium models. There is also a rather nice excursus on linear programming. A zero profit condition is imposed even when the individual firm does not enjoy constant returns to scale (p. 179). This is clearly illegitimate in an exact model and, indeed, causes the model to have an excess of equations. Model III-3, and thus later models as well, have  $\sigma$  more equations than variables (p. 179). In this case counting equations and variables could have paid off, but alas they are counted wrongly. The Hicks stability conditions are again used in a brief passage to support the same comparative statics theorems as for the exchange model. The assumption of canceling income effects is also applied as earlier. This is all as in Hicks. There is a cursory treatment of decisions under uncertainty.

Chapter 4 introduces problems of investment and planning over time. The models are closest to the Walrasian statement. Only stationary equilibria are dealt with, but a finite horizon and a succession of markets are explicitly introduced. However, quite special assumptions on the generation of expectations are needed whose import is not clear. For example, expected prices are not influenced within a given market day, and each consumer plans in each market day to liquidate all his holdings by the horizon. This last assumption seems to imply that the consumer is always revising his plans, although he is never surprised by developments (p. 212). The author rejects Friedman's criticism of Walras on saving (p. 218), so far as I can see, correctly.

A large part of this chapter is devoted to raking over the coals of ancient controversy with, I should say, doubtful profit, while the basic paper of Malinvaud [6] is nowhere mentioned. Surely much of the obscurity of capital and interest theory can be dissipated by treating present and future prices as implicit in an efficient program of production and distribution in the way Malinvaud did. This view would have been especially valuable in considering Schumpeter's arguments on zero interest in the stationary state. There is an intriguing final section of Böhm-Bawerk's arguments for the technical superiority of present goods. A closely related question has been formulated and nicely settled recently by David Gale. He shows that processes which are shorter but enjoy the same output levels result in higher von Neumann growth rates in a model where reinvestment occurs [3]. Psychological discount is defined in terms of goods rather than a one-period utility function (p. 231),

although the utility interpretation had been mentioned. Koopmans' work on this topic was presumably too recent to be introduced [4].

The Walrasian edifice is completed in Chapter 5 on the money economy. Here, too, much of the chapter is devoted to a review of controversy, this time somewhat more recent, in particular, the controversy following Patinkin's charge that classical monetary theory includes an invalid dichotomy of the general equilibrium system. In the event the author pretty well exonerates Walras of this charge, and, I think, correctly. However, he convicts Walras of another, cruder charge described earlier by Lange, the charge of observing Say's Law in the sense that the demand for increases of money stocks is set identically equal to zero for every consuming unit (p. 320). I confess that I do not think it necessary to take this view if Walras is read sympathetically. The point is, consumers in this model without uncertainty demand assets in general (i.e. "*E*"), not a particular form of asset. But, if there are no new money supplies, in equilibrium the aggregate demand for asset increments must be met by new capital goods. I find the discussion in Walras at this point quite elliptical. I also find it difficult to regard the substitution of a Cambridge quantity equation for Walras' explanation of the demand for the services of money, i.e. cash balances, as an improvement. The author uses Walras' treatment of the market in money services in an effective criticism of Archibald, who has consumers build up cash balances over a sequence of weeks (p. 317).

In Chapter 6, "The Static Linear System," there begins a series of modern developments from the Walrasian system. The Leontief input-output model and activity analysis are introduced here. The general procedure is to use the ideas of linear programming to expound these subjects. The exposition is elementary and rather well done in most places. However, for a book in economics it would be appropriate to describe in more detail the analogy between activity analysis and the action of a competitive market. The consequence of neglecting this analogy is that the crucial role of the price system for efficient decentralization of economic activity is not highlighted. The principal Koopmans result on efficiency price sets is only sketched briefly. On the other hand, the earlier interpretation of the dual of a linear program as imitating the action of competitive markets was too casual to be useful (p. 156).

Models in which space is explicitly introduced are described in Chapter 7. As elsewhere most of the exposition takes the form of a review of models presented by a series of writers, Ohlin, Graham, Isard, Lefebvre, etc. However, the chapter begins with a large-scale Walrasian model embracing the complications of investment, money, and space, albeit in simplified forms. Although it may be useful to display particular parts of the technology explicitly, this elaboration of Walras may be under a misapprehension. The author required that his simple exchange market occupy a point in space. However, it is not clear why this should be. Goods are located in places, but a market is a system of communications between persons and does not, properly speaking, have a place. This is not to say, of course, that special patterns of transport cost or barriers to trade erected by states do not deserve to be studied. Only,

the general model perhaps does not merit restating with explicit, but abstract, distinctions further enriching the subscript notations. In case 6 of spatial models (p. 448) where consumption is variable, the production point is required to minimize total transport costs. Since consumption varies, it is not easy to see what significance this solution has. Surely something like Samuelson's "net social pay-off" (p. 420) should be maximized. Case 8 is also unclear on this point. I suspect that some of the models in this chapter are summarized too briefly to be understood.

The final two chapters bring us to areas where Walras essayed some guesses but made no real progress, but where recent contributions have been substantial. Chapter 8 is devoted to dynamic models, and Chapter 9 to questions of existence and uniqueness of equilibrium. The dynamic models which are discussed in Chapter 8 include the equilibrium models of von Neumann and Leontief as well as models of multimarket disequilibrium with price adjustment processes at work of the type suggested by Samuelson. Virtually all the discussion is devoted to the statement of results. Very little is offered in the way of proofs. In the case of the von Neumann model it is the balanced-growth equilibrium which is described. There is no reference to the turnpike arguments of Dorfman, Samuelson, and Solow [2] or to any asymptotic properties of other equilibrium paths in such models. However, there is a fairly careful discussion of the difficulties met by the deterministic dynamic Leontief model. In the case of disequilibrium models, most attention is given to the consequences of assuming a stable system, and the results cited are chiefly local results. Less emphasis is placed on the Arrow-Hurwicz theorems in which certain assumptions imply global stability of the system. In particular, none of these theorems is proved.

The author appears to think that the presence of flows between processes in the economy, as described in the Leontief models, creates some difficulty for the von Neumann model, so that one must choose a sufficiently short period to justify adding flows to initial or terminal stocks (pp. 469-70). However, the spirit of the von Neumann model is that the length of the period is not relevant. The processes of the model describe possibilities of transforming stocks at one point of time into stocks at another point of time. These possibilities are well defined, whatever the flows that must occur in between and whatever the time that elapses. What the flows do is to involve a great many stocks in any single process (thus to lend some credence to the von Neumann assumption that every stock is involved in every process).

The dynamic Leontief model is not presented with complete rigor. The work of Solow [9] and Morishima [7], which would have been helpful on this topic, is not mentioned. It is not very clear what the author thinks occurs in a closed, deterministic, and dynamic Leontief model. He seems to suggest that there will be an approach to "optimal" balanced growth, although interruptions may occur along the way when rules governing disinvestment possibilities would be violated (p. 487). However, neither the optimality nor the approach seem defensible. In particular, the discussion on dominant roots is muddled. There is no reason to expect the root with largest real part to be positive, or if it is positive, it may not have a nonnegative character-

istic vector. The relevant matrix is  $[(I - A)^{-1}B]^{-1}$ . If this matrix is irreducible and has two positive roots, the positive root with a positive characteristic vector must be the smaller of the two (p. 483).

A model of dynamic behavior for the individual consumer is also introduced, but some of its features may be seriously questioned. A strategic variable is something corresponding to the Lagrange multiplier when disequilibrium prevails. It is called "marginal preference of income," but it is not defined (p. 490). The variable is needed because it is not assumed that expenditure equals income in disequilibrium. It may be possible to carry such a model through in an intuitively appealing way, but I cannot see that it is done here.

In the discussion of both the consumer and the multimarket disequilibrium models appeals are made directly to the (quite involved) Routhian stability conditions. So far as I can see, these appeals make no contribution. They are used to derive the result that stability implies that the determinant of the differential equation system has the sign of  $(-1)^n$  where  $n$  is the order of the system. However, this is obvious from the fact that this determinant equals the product of the roots, which must have negative real parts for stability.

In general, the literature of the three or four years prior to the date (June, 1962) of the preface is not used in the book. An example of the hiatus is the view that competitive exchange models may prove to be stable in all cases (p. 508) despite the publication of Scarf's counterexample in 1960 [8].

The final chapter considers the rather esoteric theorems proved in the mid-fifties on existence of equilibrium. By far the most elaborate treatment is given to the Arrow-Debreu article of 1954. Indeed, this is much the most meticulous examination of any substantial mathematical proof in the book. Moreover, most of it is well done. On the other hand, the other existence arguments (chiefly mine and DOSSO's [2]) are not clearly presented. Indeed, I fear they may be incomprehensible ("consider the set  $Y'$  defined as  $\phi([X'])$  such that when  $[X']$  lies on the boundary of feasible production,  $[Y'] = [X']$ ," p. 560).

It is said that the Arrow-Debreu Model 2 rules out fixed coefficients of production (p. 522). This is a misinterpretation. It is even possible to have universal fixed proportions in this model if labor services always have some direct utility. Also it is not true that the economic import of convexity derives only from its implying nonincreasing returns to scale (p. 524). A second important consequence is divisibility of goods. Also the nonnegativity of the price vectors is based on free disposal for goods, not just free disposal of factor services (p. 535). Finally, I do not assume in my model that consumers hold zero initial stocks of goods (p. 554). Of course, slips like these are bound to occur in so bulky a compendium. I mention them less to blame the author, than to assist the reader.

There are some errors of historical reporting in this chapter. Along with many other people, the author evidently thinks Wald only used his assumption of the weak axiom of revealed preference to get uniqueness in his existence theorem (p. 520). This is incorrect. The axiom is used also in the deriva-

tion of the existence result in the production model. Since this axiom very nearly eliminates the social feature of the demand functions, a much larger gap is left between his theorem and the recent theorems than otherwise would be the case. In Wald's theorem on exchange equilibrium greater generality is achieved, but quite special assumptions like independence of the utilities of different goods are still needed.

In commenting on the generalizations of my Graham-model theorem, the author implies that this argument is also restricted to a one-consumer economy (p. 564). This, of course, is not true. The demand function can be anything you like, so long as it is continuous and observes Walras' law. Indeed, the further statement that my proof is a special case of that of Arrow-Debreu is also wrong, since Arrow-Debreu only deal with demand functions derived from utility maximization, while mine does not require that choices be consistent, and, of course, the proofs themselves are along entirely different lines.

It may be worth while to say a word more about the method of equation-counting to lend plausibility to a general equilibrium model. This ritual is performed many times, indeed, after every statement of a model in Part II. However, this procedure does not correspond to the structure of competitive equilibrium, and in any case it is entirely indecisive. A competitive equilibrium is defined in terms of maximization of utility by consumers, maximization of profit by firms, and equality of supply and demand in the presence of a list of market prices for all goods. The basic variables are the prices. The only intrinsic set of equations are those of supply and demand, although even here it is preferable to speak in other terms. To a list of prices there corresponds a set of demand vectors, any one of which may be distributed to consumers so that no consumer can increase his utility by trading at the market prices. Call this set the demand set. Correspondingly, there is a supply set which is consistent with profit maximization by firms at these prices. Then we mean by equality of supply and demand that the intersection of the demand set and the supply set is not empty.

Whether, for example, it is possible to write down a set of equations whose solutions are the points of the demand set is quite irrelevant to the problem of whether the demand set is empty. This question should be decided prior to the attempt to construct an equation system to help in locating the set. In general, of course, no such equation system will exist, unless in some trivial sense that requires the solution to be known. But if it does, the appropriate move is to consider the plausibility of the subset of equations corresponding to an individual consumer's maximization problem in isolation from the rest of the system.

The problem on the production side is equally illuminating. It is best realized in a linear-activities model of production, which is also closest to the model of Walras. Here the maximization problem is expressed by a set of equalities and inequalities. Moreover, the inequalities are intrinsic and cannot be eliminated. These basic inequalities are, first, the nonnegativity of activity levels for the production processes, and, second, the nonnegativity of profits on all processes. There is no way of converting them into equalities without creating new inequalities. This is analogous to the presence, even

in simple interior maxima, of second-order conditions which must appear as inequalities. However the inequalities here have more than a local significance.

Thus in considering whether the system is soluble, the structure of the competitive equilibrium, implicit in its definition, suggests that one should first determine that the demand set and the supply set are well defined over some set of price vectors, and then see if there will be some price vector in this set which leads to a nonempty intersection of the demand set and the supply set. This is consistent with the approach of Chapter 9, but the methods of this chapter (on existence) and of other parts of the book where linear programming and activity analysis are discussed are not allowed to influence the development of the classical theory. Analysis along these lines would have quickly led to a revision of the system III-3 without one's needing to count equations correctly.

In the system III-3, profit-maximizing firms are subject to a 0-profit condition although they do not have constant returns to scale. This is an attempt to represent an economy of Marshallian industries which are competitive and where profits tend to be eliminated by entry and exit from an industry. The only proper way to build such a model is either to ignore the firms and deal with linear-production processes, as Walras did, or to allow the numbers of firms to vary and thus achieve approximate constant returns to scale for the group of firms of each type. Then the 0-profit condition applies to each type of firm, and the number of firms of each type is a new variable, corresponding exactly to the activity level in the model with linear processes.

*A Study of Cost and Demand Inflation.* By J. D. PITCHFORD. Contributions to Economic Analysis XXXIII. Amsterdam: North-Holland Publishing Co., 1963. Pp. 167. \$4.20.

The purpose of this book is the examination of cost and demand inflation. To achieve this purpose, J. D. Pitchford has devoted the bulk of its pages to the working out of the implications of several simple models of inflation.

He first develops a "basic model" of an aggregated and closed economy in the very short run. The main characteristics of this model are: (1) Wages depend upon both demand and "costs." The change in wages is a function of lagged excess demand and lagged prices. (2) Prices depend upon both demand and wages. The change in prices is a function of lagged excess demand and lagged wages. (3) A change in prices and wages leads to a less than proportionate change in money aggregate demand. This ensures that the price level is determinate.

In examining the implications of this model, the author develops the concept of income claims. These are the proportions of national income implicit in the markups on costs in the wage and price equations. If the wage and profit claims are consistent (i.e., they do not add up to more than one), the stationary value of the price level will also be an equilibrium one in the sense that excess demand and unemployment will be zero. If the claims are excessive, prices and wages will come to rest only if enough excess supply and unemployment have been created to dampen the cost pressures.

In this model the relative "bargaining power" of wage and profit receivers does influence the share of income each receives. When income claims are inconsistent, labor's share will increase as cost-determined wages become more important or as demand-determined prices become more important.

After nine variants of this basic model (involving different combinations of pure demand, pure cost, and cost and demand wages and prices) are examined, a disaggregated model is constructed. This model has two commodities and two groups of workers. One price and one wage are demand-determined, the other two are cost-determined. Once again excessive income claims result in a stationary price level above the equilibrium level, but deficient demand and unemployment will be concentrated in the cost-determined sectors.

Further elaborations of the aggregative model involve introducing some flexibility in income claims—i.e., making them responsive to aggregate demand and enlarging the model to include foreign trade.

The main contribution of this book is its clarification of the role of cost-plus pricing and cost-of-living wage adjustments in inflation. Pitchford has demonstrated that the existence of such price and wage behavior alone does not create incompatibility between price-level stability and full employment. Whether the income claims are consistent is of crucial importance. In his own words:

If too much attention is devoted to methods of determining prices and wages the paramount issue of excessive or consistent income claims may be

neglected. It is not the type of price fixing that matters, but whether or not the claims of the two recipients can be mutually satisfied (p. 57).

Beyond that, the book is somewhat disappointing. While the dynamic aspects of the inflationary process are not completely ignored, comparisons of stationary positions receive heavy emphasis. The speed of the inflation is surely at least as important as the eventual stationary price level, especially from a public policy standpoint. Since the response of prices to changes in demand will depend upon the extent of cost-determined pricing, emphasizing the effects upon the stationary value of the price level can be misleading.

The whole study is completely divorced from the business cycle, thereby ignoring factors of importance for inflation, such as the cyclical behavior of productivity and the late-recovery profit squeeze. It would be interesting to examine the behavior of Pitchford's model with excessive income claims in a cyclical context.

Since excessive income claims account for the incompatibility of full employment and price stability in his models, the author devotes one chapter to an examination of the sources of these claims. Unfortunately, nothing particularly novel emerges from this discussion. The highly aggregative approach embodied in most of the simple models probably accounts for the inadequate treatment of structural problems arising from excessive sectoral demands and price and wage rigidities. The interactions between product market conditions and labor market conditions which Levinson found to be important are not dealt with at all.

The chapter on policy provides no new recommendations for dealing with cost inflation. However, the author correctly points out that an "incomes policy" necessarily involves implementing a particular income distribution, a point which some supporters of the Council of Economic Advisers' "guideposts" appear to have overlooked.

*Models of Income Determination.* National Bureau of Economic Research, Studies in Income and Wealth, Vol. 28. Princeton; Princeton University Press, 1964. Pp. ix, 427. \$10.00.

The focus of this income and wealth conference was on models intended to explain major national income components. As seems inevitable with conference proceedings, the papers vary greatly in scope, technical level, and quality.

The most ambitious and comprehensive model is presented in the first paper, "A Postwar Quarterly Model: Description and Applications," by Lawrence Klein. Klein's model contains 29 endogenous variables and is estimated from quarterly data for the years 1953-58. This model is clearly a descendent of earlier models estimated by Klein and his collaborators and improves on earlier work in a number of ways. It is impressive how much he has been able to incorporate the best recent work on production functions, inventory accum-

ulation, etc., in the present model. A major part of Klein's paper is concerned with a detailed analysis of forecasts, completed in April, 1961, for the second and third quarters of 1961. The model correctly predicted the upturn in the second quarter of 1961 and predicted most GNP components with considerable accuracy.

The second paper, "A Forecast Determination of National Product, Employment, and Price Level in Canada from an Econometric Model," by T. M. Brown, gives the first full presentation of the econometric model of the Canadian economy developed at the Department of Trade and Commerce. This is an annual model estimated from the years 1926-41 and 1946-56. The model contains 40 endogenous variables but, as Christ shows in his comments on Brown's paper, can be reduced to eight independent stochastic structural equations in eight endogenous variables. An impressive amount of work has gone into the construction and estimation of the model, but it leaves a strong over-all impression of being less up-to-date than Klein's model in that it incorporates much less of what has been learned from earlier postwar econometric models. Like Klein, Brown focuses on the forecasting accuracy of his model, using the recession year of 1958 as the forecasting period.

The third paper, "Income and Asset Effects on Consumption: Aggregate and Cross Section," by Jean Crockett, is a study of the determinants of household expenditure patterns. Attention is focused on three sets of considerations: (1) separating the effects of permanent and transitory components of income; (2) measuring the interaction effects of income and assets; and (3) taking account of different tastes that presumably exist among different families. The paper contains a wealth of suggestive results obtained from cross-sectional and time-series data. The thorniest problems arise under (3), in trying to measure the degree of thriftiness of different families. Causation does not flow uniformly from income to saving and consumption. Instead, income, consumption, and the forms of asset accumulation should all be endogenous variables in a model that contains the demographic, economic, and sociological variables that measure tastes for and availability of those endogenous variables.

The next paper, "Capital Expenditures, Profits, and the Acceleration Principle," by Robert Eisner, is a contribution to the empirical estimation of accelerator models of capital investment decisions. Eisner makes use of his well-known distributed lag investment function and employs a large sample of capital expenditure data collected by the McGraw-Hill Publishing Company. Eisner's model performs well with these data in comparison with several alternatives, but the multiple correlation coefficients are distressingly small. A notable feature of Eisner's paper is his discussion of the relation between accelerator and profit-maximization models. The discussion between Bert Hickman and Eisner is enlightening on this point.

"Determinants of Inventory Investment," by Michael Lovell, is a thorough and useful survey of the extensive research now available on the determinants of inventory investment. Attention is rightly focused on the role of sales expectations in the making of production and inventory decisions, and

Lovell evaluates the major contributions to this problem, including his own important work.

In "The Federal Sector in National Income Models," Wilfred Lewis, Jr. discusses a variety of topics related to the federal sector. Relationships are estimated between corporate income tax receipts and corporate profits, between personal income tax receipts and disposable income, between excise tax receipts and GNP, and between social insurance contributions and wage and salary payments. Projections of total receipts in the federal sector are made to 1970. Several projections of federal expenditures are compared and evaluated. The theoretical discussion of the determinants of federal spending, based on the "displacement effect" of wars, is unrevealing. Some of Lewis' comments, especially on page 248, sound dated in view of the 1964 tax cut. Finally, Lewis attempts to measure the effects of the built-in stabilizers in the federal fiscal system. Hickman shows in his comment that Lewis' measures are marred by biased estimates of marginal consumption propensities.

"Short-Run Forecasting Models Incorporating Anticipatory Data," by Irwin Friend and Robert Jones, is an attempt to persuade the reader that short-term forecasting is better attempted with a carefully chosen small-scale model than with one of the large-scale models that have been presented to the profession. Their evidence in support of this proposition is a comparison between the forecasting properties of their four-equation model and those of several larger models, in particular Klein's quarterly model discussed above. Their argument makes frequent use of innuendo (for example, their false contrast on page 280 between models which concentrate on a small number of basic variables and those that contain a large number of marginal variables). Furthermore, their substantive procedure is inadequate. They compare their *ex post* estimates and forecasts with Klein's *ex ante* estimates and forecasts. Neither we nor, possibly, the authors know how much their knowledge of events during the forecast period affected their choice of models and estimates. Comparing the forecasting accuracy of econometric models is a subtle and complicated problem which has been studied by Theil and others. Friend and Jones have not done justice to this problem.

"An Empirical Model of the United States Economic Growth: An Exploratory Study in Applied Capital Theory," by Albert Ando presents a disaggregated neoclassical growth model. One consumption good and an arbitrary number of capital goods are assumed to be produced with Cobb-Douglas production functions in each of which all the capital goods appear as arguments. Disembodied technical change is assumed in each sector. The generalized model permits Ando to obtain richer results, particularly regarding price relationships, than is possible in a one-commodity model. The discussion of measures of the aggregate capital stock (pp. 347-54) is particularly interesting. Estimation from data for periods 1900-1928 and 1951-58 is attempted for the special case of one capital good and one consumer good. Although the empiricism appears to be somewhat casual, the results are plausible and suggestive.

In "Notes on the Measurement of Price and Quality Changes," Zvi Gri-

liches surveys and extends his earlier research on the measurement of quality changes, particularly in postwar U.S. automobiles. Price differences at a point in time between cars with different quality combinations permit him to estimate the cost of changes in various qualities such as length, horsepower, etc. Using these estimated quality change costs, he can correct year-to-year price increases for quality improvements. The method is ingenious and appealing, but the ability to identify relevant qualities is crucial for practical application. A strong case can be made in principle for concentrating on performance characteristics (such as the number of trouble-free miles, fuel consumption per mile, etc.) rather than on physical characteristics. Presumably, for example, it is not the weight of the car that provides utility, but the resulting safety, comfort, etc. Some physical characteristics may be good proxies for the more basic performance characteristics, and some may not. Griliches has opened up an area in which a great deal of useful work can and should be done.

One concluding remark may be in order. It is incredible how much of the effort and trouble in short-term forecasting models (including the papers in this volume by Klein, Brown, Lovell, and Friend and Jones) is related to inventories and inventory investment. Perhaps the American Economic Association should offer a \$1,000 prize to the first economist who submits a model that will accurately forecast the inventory component of the national income accounts.

*Intermediate Price Theory.* By SIDNEY WEINTRAUB. Philadelphia and New York: Chilton Books, Publishers, 1964. Pp. xiv, 378. \$8.00.

*Intermediate Price Theory* is a revision of Sidney Weintraub's book, *Price Theory*, first published in 1949 by the Pitman Publishing Corporation. The intent of the earlier work was to provide a treatment of price theory for relatively advanced students. In the current edition, as suggested by the new title, the avowed purpose is to simplify the exposition and so to serve a wider audience. To this end what was needed was a careful, chapter-by-chapter revision; what is achieved falls short.

Briefly, the revision entails the deletion of a number of chapter sections, the deletion of the bibliography at the end of each chapter, some shuffling of the remaining chapters and sections, the addition of exercises throughout the text, the addition of short expositions of topics of recent interest, and the addition of some exposition of welfare economics. Little rewriting is attempted; a close examination of the original text reveals only minor changes here and there, introduced largely to facilitate the deletions and the shifts in organization in the new text.

More particularly, the bulk of the deletions occurs in reducing Part IV, "Dynamic Analysis," from five chapters to two chapters and, similarly, in reducing four of the chapters in Part III, "Market Behavior of the Firm," to two chapters. Apart from transposing a number of chapter sections, the major change in organization is to locate the exposition of consumer behavior after,

rather than before, chapters on market demand and production and costs. Revealed preference, von Neumann-Morgenstern utility, general equilibrium, input-output analysis, and linear programming are introduced as new topics. Each of these treatments, however, is too brief to be of much service. For example, about three pages each are devoted to expositions and evaluations of revealed preference and von Neumann-Morganstern utility. Similarly, about nine pages are now allotted to sketching the equations of general equilibrium and a few pages each to input-output analysis and linear programming. Of these short digressions, the expositions of input-output analysis and linear programming are hopelessly opaque. More favorably, a concise, reasonably clear exposition of Pareto Optimality in the guise of two-person, two-commodity exchange and production is also added and used subsequently in drawing welfare implications of various types of competition. The net result is that most of the original volume is reproduced unchanged, with additions being negligible except for the exposition of welfare economics.

The extent of the revision, consequently, is minor, and the objective of simplifying the exposition has not been realized. The suitability of the new edition as an intermediate price theory text thus hinges on the content of the original volume.

Several reasons support the contention that a careful, chapter-by-chapter revision was needed to provide a useful intermediate price-theory text. One reason is to be found in the author's intent in 1949 to present an advanced statement of price theory. While the exposition itself is not especially difficult, relying heavily on geometric and literary devices, an effort has been made to canvass much of the literature of the 1930's and 1940's on imperfect competition, and the outcome has been an exposition which treats too many special cases and too many fine points to serve the needs of students with only a limited background in economics. Another important drawback is the author's tendency to intermingle his own personal critique of price theory along with generally accepted reservations. Too often the reasons for criticisms, their degree of consensus, and their force, after taking into account developments in economic theory not discussed in the text, are neglected. Blatant examples are the author's outright biases against general equilibrium analysis and the use of mathematics in economics, discernible in the earlier text but now asserted even more baldly. (Cf., particularly, pp. 155-56 and 162-64.) Only a good background in the literature, not only of the 1930's and 1940's but of earlier and later periods, would enable the student to thread his way through the exposition and to isolate and give due weight to the author's own evaluation of price theory. To increase the difficulty for the student, a number of technical errors and ambiguities and dated modes of exposition have been carried over unchanged from the original volume or introduced here for the first time. Some examples are the following: the definitions of homogeneous and nonhomogeneous production functions are incorrect; the distinction between cardinal and ordinal is never clearly drawn; the short section on instability in Chapter 6 is exceptionally ambiguous; the mistaken impression is given that indifference-curve analysis is limited to choices

between two goods while holding the consumption of other goods constant; substitutes and complements are discussed in several ways, but the definition in terms of the substitution effect of a price change is not mentioned; the inequality condition that price equal or exceed average variable cost is confused with the second-order condition for profit maximization; an incorrect bit of mathematical legerdemain is used to show that the marginal rate of product transformation equals the ratio of marginal products. The conclusion I am forced to draw is that, on a variety of grounds, the new edition is not the book to be offered to an intermediate price-theory student.

*Income: Analysis and Policy.* By MYRON H. ROSS. New York: McGraw-Hill Book Co., 1964. Pp. viii, 431. \$7.50.

This is a textbook whose chief use will be in undergraduate macroeconomic courses just beyond introductory economics. There have already been many other textbooks written to serve this use; no fewer than eleven—those by Ackley, Bailey, Dernburg and McDougall, Greenhut and Jackson, Henderson, Peterson, Powelson, Rosen, Siegel, Sirkin, and Walker—have been reviewed in this journal during and since 1961. And much of the subject matter included in these books is also treated in the numerous recent texts on introductory economics, money and banking, growth, public finance, and business fluctuations. What then is the justification for the appearance of still another book dealing with this same subject matter? What is there about this new book which should induce a teacher to choose it rather than any of its competitors? Are the earlier books so quickly outmoded by the swift onslaught of events and thought? Are they so deficient in exposition? Does each of them include so inappropriate a compendium of topics? Is it so important to provide a wide variety of books from which teachers may choose?

The topical sequence of this text does not differ significantly from many of the others in the field. The first two chapters (11 per cent of the book) define and discuss the concept of income—money, real and psychic—and explain how it is accounted for in the United States. Chapters 3 through 9 (40 per cent) present the accepted Keynesian, classical, and Hicksian neo-Keynesian (part of which Ross unfortunately chooses to label "Klassical") theories of consumption, investment, interest, income, and employment. Chapters 10 through 12 (20 per cent) are primarily concerned with theories of growth, cycles, and inflation. Chapters 13 through 17 (20 per cent) are about the use of monetary and fiscal policy to achieve macroeconomic goals. Chapters 18 through 20 (9 per cent) appear as afterthoughts concerning personal income distribution, international economic relations, and the history of economic ideas other than those Keynesian and classical.

Perhaps the chief merit of the book is its clear exposition. Students will find it easy to grasp quickly most of the points which are made as they are made. There are excellent summaries at the end of each chapter and an above-average consistency of terminology and symbolism throughout. The

expository quality would have been even better if there were set out explicitly somewhere a complete table of symbols and their definitions; as it is, the reader must, for example, frequently ponder and/or search for the meaning of  $t$ . The generally good exposition occasionally breaks down as in the explanation (pp. 86-87) of the inverse relationship between the amount of investment and the expected marginal rate of return on investment (that is, the explanation of the negative slope of the MEC curve). In this explanation there is multiple confusion for the reader partly because Ross, having previously defined  $r$  as the rate of profit, now seems to treat it as the rate of cost of borrowed funds and partly because there is in no place a complete enumeration of the causes of shifts in the curve as opposed to causes of movements along the curve. Another example of poor exposition appears in the discussion of the Duesenberry effect and the short-run or cyclical marginal propensity to consume (pp. 56-57); it is left unclear whether Ross means that in a recession consumption will decrease only slightly relative to the decrease in income because "families are willing to sacrifice savings in order to protect their living standards" or rather that he means that consumption will decrease greatly relative to the decrease in income because "In recession, consumers are generally in a defensive state of mind. . . ."

One may also quibble with Ross about both his sequential order of topics and his exclusion of some topics. As a means of exciting interest among most students, an opening with two chapters of definitions and conceptual abstractions is perhaps not the happiest choice. Even at the intermediate college level it seems more motivationally effective to begin by describing the pressing social problems whose character and solution should provide the *raison d'être* both for the book and for the study of it. And in general the book seems to display too much concern with income itself and too little with those problems—unemployment, inflation, and growth—for the study of which income analysis is merely a tool. Moreover, throughout the book there is too little empiricism and history, and what there is, is too often segregated out and presented as merely incidental. Symptomatic of this de-emphasis of empiricism is the persistent use of hypothetical rather than historical data in numerical illustrations. In addition, and not surprisingly, the book seems to place a disproportionately small emphasis upon programs to increase income, employment, and growth by means other than conventional fiscal and monetary policy. Very little of the current antipoverty program involving such things as retraining, regional redevelopment, and geographical mobility of resources is discussed. Another significant failing is the omission of a discussion of the determinants of state and local government spending in the theoretical chapters dealing with the determinants of aggregate effective demand. These spending units, as well as households and businesses, deserve treatment. It may even be that federal government, whose spending is determined in considerable part by factors other than the desire to achieve full employment, price stability, and growth, should also have been treated in the theoretical chapters.

The adverse criticisms of the previous paragraphs should not be permitted

to obscure the fact that this reviewer regards Ross's text as a good one. Ross obviously knows what he is writing about; his discussions are scholarly and, for the most part, his opinions well balanced. His text achieves a greater degree of integration of material than do most; the reader is considerably helped to see how things fit together. All in all, one can with a clear conscience recommend the book as worthy of consideration for use.

*Rich Man, Poor Man—The Distribution of Income in America.* By HERMAN P. MILLER. New York: Thomas Y. Crowell Co., 1964. Pp. xxi, 260. \$4.95.

This book contains an analysis of factors determining the distribution of income in the United States largely using data obtained in the U.S. Census of 1960. Chapters are devoted to discussions of income classified by color, occupation, education, and wives' work experience. An analysis of the poorest fifth of U.S. families is made by considering the categories of farmers, aged, broken families, nonwhite families, and other groups among the 9.6 million families making less than \$3,000 in 1959. The problems of single males or young single males are not stressed, presumably because the unit examined was the family.

A strong emphasis is placed on the effect of discrimination. The author shows in an important table that the median income of Negroes was 52 per cent of the median income of whites in 1959 and that this ratio was the same as it was in 1949. A classification by state shows that the Negro-white median income ratio actually decreased from 1949 to 1959 in most of the states having large numbers of Negroes. Another table shows that the non-white-white income ratio for males, classified by amount of education, decreases as the amount of education increases. In 1959 the average nonwhite with four years of college could expect to earn less during a lifetime than the white who did not go beyond the eighth grade. One wishes these educational classifications had also been cross-classified by region. A special plea is made in the final chapter for the elimination of discrimination in employment, housing, and education. The author states, however, that the elimination of discrimination would still leave economic hardship since one of every five Negroes grows up in a fatherless home.

The most important thesis of the book is that when one considers inequality of income in the United States, "There has been no appreciable change in income shares for nearly twenty years." The author offers as evidence one table giving the share of total personal family income received by families in each quintile range in the years 1929, 1935, 1941, 1944, and 1961. The percentages by quintile range are the same in 1944 and 1961. However, these results are somewhat puzzling when one compares them to the data of another recent publication, *Trends in the Income of Families and Persons in the United States* by Herman P. Miller. In this publication, the income concept is that used in the Current Population Survey of the Bureau of the Census. Here the published Gini coefficient of income inequality for families de-

creased from .378 in 1947 to .351 in 1957.<sup>1</sup> This is a 7 per cent movement toward a Gini coefficient of zero or perfect equality. The increase in the coefficient from .351 in 1957 to .369 in 1960 is consistent with the increased unemployment rate after 1957. In evaluating the impact of unemployment, the 11 million unrelated individuals not included in families should be considered. A perhaps more adequate distribution is that for males 14 years old and over with income. In this case the published Gini coefficient increases from .413 in 1947 to .438 in 1960.<sup>2</sup>

What is even more important is that when the lowest 20 to 40 per cent of males or families are eliminated from their respective distributions, inequality decreases from 1947 to 1960.<sup>3</sup> Thus, decreasing inequality may have continued in the last 15 years except for low-income groups. This decrease focuses the problem even more on the plight of the low-income group. It is more than a problem that the relative poor are with us. It is, rather, a problem of the share of total income received by the relative poor.

The author is clearly in sympathy with the plight of the poor man. He suggests in general terms that the unemployed must be aided so their training and mobility are strengthened. Cases of individuals with economic problems are described in detail in several parts of the book. The author argues that the individual in a democratic society can demand the chance to develop his talents and to have a floor to his income so as to minimize his suffering.

This easily read book is written at a level where it should have wide circulation in publicizing the problem of income distribution.

*The Origins of Scientific Economics.* By WILLIAM LETWIN. London: Methuen and Co., 1963. Pp. x, 316.

According to the author, scientific economics is deductive economic theory, operating with a small number of principles and capable of explaining many diverse economic phenomena. This scientific economics did not grow by "mere idle accumulation," but was "invented" in the late seventeenth century. However, it was not a product of deliberate scientific intention—Sir William Petty's claims for his political arithmetic notwithstanding—but rather a by-product of men's efforts to convince others of the desirability of certain economic policies. "The needs of rhetoric brought forth the method of economic theory." As William Letwin says in the preface, his purpose is to show how "practical, and often mercenary objectives led certain men to build a new science, the first social science."

The declining authority of the Church and of theological pronouncements

on economic questions had opened the door to an economics that was independent of accepted religious and ethical considerations. In seventeenth-century England, especially after the Restoration, writers on economic problems confronted an audience that was intensely suspicious of economic advocacy in terms of the general interest. The group of men best suited by experience and inclination to write on economic questions were likely to be men with business interests, and these men were especially vulnerable to the accusation of special pleading and mercenary motives.

How to disarm this seemingly ever-present and intractable skepticism of the reading public was a major problem. Ardent professions of preferring the public over one's private interests could be expected to meet with scornful rejection. Recourse to anonymous publication was frequently practiced, but it was more likely to stimulate than to allay suspicion. Thomas Mun was prominent among the merchants who sought to strengthen their credibility and authority by arguing that the King's interests and the interests of the merchants usually coincide, and hence that the public interest was most likely to be promoted by attending to the counsel of businessmen. The difficulty with this approach was that merchants so frequently disagreed on the policies they recommended and on what they held to be important. Who among them could be trusted, and whose voice was the voice of authority?

The dilemma was resolved as economic writers evolved an impersonal and objective form of argument and analysis. Dudley North best illustrates the new style, and his brief "Discourses"—almost unknown to contemporaries—are the peak of economic thought during the seventeenth century, according to Letwin. It was his younger brother and biographer, Roger North, who called attention to the great differences between the style and temper of Dudley North's economic analysis and that of his merchant colleagues. No one escapes partiality to his own interests, but by building the analysis upon "clear and evident truths" and reasoning from these "principles indisputably true," we can arrive at correct conclusions. A taut deductive system that reaches its conclusions from a simple set of principles was Roger North's prescription for the necessary objectivity with which to dispel the charge of special pleading, and it is this method of analysis that gains recognition as scientific economics.

Not all readers will be prepared to accept the author's definition of scientific economics or the particular explanation he advances for the rise of this scientific economics, but most of them will agree that he has written a stimulating and informative book. He confines himself almost entirely to British experience, and within this area he concentrates his analysis and discussion largely on Child, Barbon, Locke, Collins, Petty, and North. The first two represent the "old style" economics, and the others illustrate the "new style." The book is a happy combination of thorough scholarship and imaginative writing.

*Economic Growth—An American Problem.* Edited by PETER M. GUTMANN. Englewood Cliffs, N.J.: Prentice-Hall, Inc., 1964. Pp. 181. \$4.50.

This volume in Prentice-Hall's "Modern Economics Issues" series, under the general editorship of Otto Eckstein, is ostensibly "aimed at everyone who is concerned about the pace of American economic growth as compared to that of other countries." The readership target, as thus defined, is blurred; the actual pitch of the book, to the extent it can be said to possess a uniform level of sophistication, is in the reviewer's judgment a bit over the head of the educated layman. It will be useful for the second term of a first-class university introductory economics course or for U.S. economic history courses in which introductory economics is a prerequisite.

The other countries with which the United States is compared turn out to be almost exclusively the Soviet Union. Of doctrinal and theoretical background selections, the volume is unfortunately bereft. There is a moderate amount of duplication. Regrettably, there is no index.

Slightly over one-fourth of this brief volume is accounted for by material very familiar to economists: a condensation by Edward F. Denison of his own *Sources of Economic Growth in the United States*, Theodore Schultz's December 1962 presidential address before the AEA on "Investment in Human Capital," and sixteen pages from the 1962 *Annual Report* of the Council of Economic Advisers. Another fourth of the volume is accounted for by a long, uninspiring, but helpful, panoramic lecture on growth anatomy by Peter Gutmann. An informative 22-page essay by Stanley H. Cohn on U.S.-Soviet growth comparisons carries us up to almost two-thirds of the book. For most of the rest, there is a somewhat chatty and frequently incisive piece by Robert M. Solow; some descriptive material on research and development; a vignette on fiscal policy by Otto Eckstein; what may come to be known as "Samuelson's 22 Points" on fiscal and financial policies (for growth, of course); and a significant essay on the postwar Kuznets cycle by Edward M. Bernstein. The impediments to growth are presented by the Chamber of Commerce of the United States and are, of course, alleged to be heavily governmental in origin.

The Bernstein discussion supplies this book's explanation of the slowdown in U.S. economic growth (or, more properly, in intermediate period expansion) after the mid-1950's. The slowdown is presented as a normal Kuznets downswing. For a period still too short to give us decent answers to trend questions, the Kuznets cycle apparently does just as handsomely or poorly as the Kondratieff long cycle did for Schumpeter in rebutting the stagnation hypothesis as applied to the Great Depression of the 1930's. The impact of Bernstein's analysis is given a coda, in the very last selection, by Eckstein's confession that he sees "no reason to accept the most pessimistic of the theories, that of secular stagnation" (p. 177). If we are going thus to write off a hypothesis of secular stagnation in the private market mechanism, insofar as it is possible any more to disengage analytically that mechanism from the public budgets, shouldn't we do it explicitly, and for some attempted

good reasons? Similarly for Schumpeter's theory of crumbling walls, also ignored in this work.

This criticism of the handling of secular decline is underscored by the book's lack of treatment of the possible implications of the apparent upward secular trend in the output-capital and the incremental output-investment ratios. The book's only treatment of the prospects for private capital formation as a growth determinant is a superficial substitution of statistical projections for economic theory. The related question of the future role in economic growth of government expenditure and debt is by-passed in Eckstein's essay, which presumably should have dealt with it. Even Samuelson's 22 Points, while scarcely revealing any emphasis, suggest several stimulants to *private capital formation*, even while noting, somewhat disparagingly, that the classicals "tended to place all their emphasis on capital formation as the sole source of progress." Many other propositions, some of them refreshingly succulent, can be found in Samuelson's list.

In general, the book gets a rather low excitement rating because it skirts fundamental theoretical controversy regarding U.S. growth problems and prospects in favor of description. A gentle exception to this criticism is the entertaining treatment by Solow of the differing opinions between the three-percenters and the four-percenters. (He concludes the argument is not solidly based.) On the other hand, if one wants largely description and suggestions as to the many aspects of growth, these pages yield a fairly generous portion. "Everyone" who is getting into theoretical questions on this subject will at least wish to be familiar with the sort of material contained in this book, if he is not already.

*Economic Growth in France and Britain, 1851-1950.* By CHARLES P. KINDLEBERGER. Cambridge: Harvard University Press, 1964. Pp. xii, 378. \$8.95.

Economics, said Cannan, is a serious subject. Can the same be said of economic history? Charles Kindleberger thinks not: "Economic history, like all history, is absorbing, beguiling, great fun. But, for scientific problems, can it be taken seriously?" (p. 332).

In essence his book is an essay in criticism. Kindleberger explicitly disavows credentials as an economic historian. He relies exclusively on secondary sources, which he subjects to detailed logical analysis and compares with one another in an attempt to evaluate their explanations of French and British economic history of the past century. He devotes the greater part of the book to what he calls "partial equilibrium" analysis, with chapters on each of the potential determinants of the level and rate of change of economic development: resources, capital, population, social factors (values, religion, family and class structures, etc.), entrepreneurship, technology, and the role of government, discussing its probable effects on economic growth. He also deals

in separate chapters with some specific sectors and structural features: agriculture, foreign trade, scale and competition, urbanization and regional balance, leading and lagging sectors and industries. Finally he considers the extent to which the patterns of growth may have been determined or influenced by such random exogeneous factors as harvest variations and wars, and concludes with a brief, summarizing "search for a method."

At the level of the individual chapters Kindleberger's treatment is superb. Although he eschews primary sources, he has digested an enormous amount of secondary literature, in the French case especially. Factual errors are few and mostly unimportant, although it is certainly incorrect to say that French agriculture in general is backward today (p. 217; see Gordon Wright, *Rural Revolution in France* [Stanford 1964]), or that "after World War I Britain thought that defeat of . . . Japan had removed its major international competition" (pp. 319-20). Kindleberger's logic is usually impeccable on matters of detail, although he gets himself involved in circular reasoning in his discussion of French coal resources (pp. 17-23). Not least important, Kindleberger writes with verve and force, if not always with fairness to the authors he criticizes. In short, economists with little prior knowledge of French and British economic history will learn a great deal from the book and will enjoy reading it as well—especially if they have an innate bias against economic historians.

In spite of these substantial merits, the book as a whole is not only disappointing but obscurant, not merely "negative and paradoxical" as Kindleberger himself describes it (p. 3). One suspects, in fact, that he set out to write a somewhat different book. Internal evidence as well as a letter from the author to the reviewer in 1958 suggest that Kindleberger originally intended to set economic historians straight on the causes of the relatively slow growth of the French economy over the last century or so. (The inclusion of Britain as a "control" may or may not have been an afterthought, but the discussions of the British experience occupy far less space than those on France and are based on a much narrower selection from the relevant literature.) If so, the task proved more difficult than his presuppositions led him to expect. In Kindleberger's view none of the explanations that have been offered to account for the patterns of French and British economic growth and stagnation is satisfactory, but he can provide no general explanation of his own. Instead he is led to a blanket indictment of economic history in general (or is it economic historians?). "What has been revealed is the virtual impossibility of proving anything positive about theories of growth through the use of history, and the propensity of economic historians, with rare exceptions, to overgeneralize" (p. 324).

The indictment will not stick, however. What theory could possibly be "proved" by historical evidence? Most economic historians, insofar as they are competently trained in their profession (but of course not all are), use theory to *interpret* the evidence. Moreover, as Kindleberger himself points out, "The difficulty is that there is no single theory of economic growth . . ." (*ibid.*). Are economic historians to blame for that? One is reminded of the fable of the hedgehog and the fox: the fox knew many things, but the hedge-

hog knew one BIG thing. Economic historians are foxes: they know many things. Kindleberger wants to know that one big thing, and, in effect, blames economic historians for hiding it from him. Most economic historians would agree that a "single theory of economic growth" not only does not, but cannot, exist in any meaningful sense. Kindleberger, however, accuses them of using "partial theories as if they had total validity" (p. 325). This is surely an example of the kind of overgeneralization for which he stigmatizes economic historians. The more usual criticism of economic historians is for failure to generalize at all. In spite of abundant footnote documentation throughout the volume, the section entitled "Single-Valued Explanations of the Alleged Slowness of French Growth" (pp. 8-10) does not contain the name of even one author of such a "single-valued explanation"—nor does any other page. Those anonymous authors are, in fact, straw men.

This is not to say that Kindleberger might not have named the names of some authors of highly oversimplified or self-contradictory generalizations about French or British economic growth. (But if he had, not all of them would have been economic historians.) Before issuing his blanket indictment, however, he might have been more careful to distinguish those who, being neither good economists nor good historians, fail to recognize the complexity of their subject matter and deal with it as if it were a simple algebraic model or a tale to be told. Serious economic historians have long since given up the search for "single-valued" explanations of economic change. If Kindleberger's excursion into historical analysis has brought him around to that position, he is to be congratulated on having proved that history is not entirely useless.

The discipline of economic history today stands in much the same relationship to economics as social science generally does to natural science. The number of relevant variables is enormous, the manner of their interaction extremely complex; the difficulties of accurate measurement are formidable, and the cost of gathering data is great. Moreover, the economic historian has a dual task: he must both gather his own data and attempt to organize them in a coherent manner. Given the brevity of life, the scarcity of financial and institutional support for economic history, and the variety of interesting problems that beckon, it is not surprising that some individual scholars either never generalize or attempt to generalize too soon on the basis of inadequate data—the latter failing is not unknown to other branches of the profession with less difficult data problems. This is not meant to exempt economic historians from criticism: their work should be judged and criticized by the same criteria that apply to that of other economists. But to castigate its practitioners because their subject matter is difficult is not only irrelevant but ridiculous. As a critic of economic history, can Kindleberger be taken seriously?

*Economic Growth in the West—Comparative Experience in Europe and North America.* By ANGUS MADDISON. New York: Twentieth Century Fund, 1964. Pp. 246. \$4.50.

There is much food for thought in this volume by an author who has been

a staff member of the OEEC-OECD for the past 11 years. Angus Maddison attempts to explain why and how the European economy accelerated its growth in the 1950's; why the United States has not shared in this acceleration; and why the performance of some European countries has been "better" than others. His study "did not arise from any desire to theorize about growth, but out of a practical interest in forecasting what the future development of the Western industrial economies would be." His theoretical framework is extremely simple and is based upon the Harrod-Domar identity: the rate of growth of output is the ratio of investment to output divided by the marginal capital-output ratio.

To explain economic growth in the West, one must explain the growth of output per man-hour. From 1870-1913, 1913-50, and 1950-60 the growth of productivity accounted for 71 per cent, 90 per cent, and 83 per cent of the growth of output.

His thesis is as follows:

1. The maintenance of high and stable levels of demand has been the major reason for the improved performance of the European economies as compared with the past and is part of the reason why they have grown faster than the United States.

- (a) The investment-output ratio is negatively related to the risks of investment. Confidence in the maintenance of full employment has induced businessmen to maintain higher investment-output ratios than prevailed in the past.

- (b) The impact of technical progress depends largely upon the age of equipment and the rate of investment. With the adoption of new and improved technologies as a result of investment which lowers the average age of equipment, the marginal capital-output ratio need not increase. On the other hand, investment is more likely to produce capital-deepening and a rise in the marginal capital-output ratio in countries which already have the most up-to-date technologies.

- (c) The rate of increase in employment was higher in Europe in the 1950's than in earlier periods; and it was particularly high in the fast-growing countries. When there is an ample growth in the supply of labor, output could be increased without a rise in the marginal capital-output ratio. A high level of aggregate demand was necessary to convert the growth of the supply of labor into the growth of employment.

2. Under conditions of full employment, the author believes that the European economies will grow at higher rates than the U.S. economy, because the U.S. productivity level is twice that of Europe. Most of this productivity gap is due to missed investment opportunities: the European countries are working below the fringe of best-practice technology, and they also have lower capital-labor ratios than the United States. For many years Europe had the potential for high growth, but the failure of an adequate level of aggregate demand prevented the economy from growing at its capacity rate during the earlier periods.

3. Success in the 1950's was often due to luck rather than to policy. "For most of the 1950's, European governments made their policy decisions with-

out any quarterly estimates of national income, and without benefit of seasonally adjusted figures for other key indicators. In many cases, forward indicators, such as order figures were not collected. There was little effort to set up the budgetary accounts in such a way as to quantify the impact of discretionary policy measures as distinct from the impact exerted by the existing tax structure. There is such a heterogeneity in government accounts that it is not possible to compare the effect of policy in different countries in any quantitative way." But nearly all European countries sustained a buoyant level of demand, whereas in the United States policy was lacking in this respect.

4. Maddison feels that governments should have a growth policy that would manage over-all demand and the price level to ensure full employment. He specifically advocates "an articulate effort to define the potential of the economy and to see that resource allocation, particularly investment, is adequate to reach this. These ends are complex and cannot be achieved by getting a tax structure that automatically provides built-in growth or built-in stability. Policy will have to be pretty continuously active, although the need for intervention will vary between countries with different problems and institutions."

There are many questions posed by the author which are not satisfactorily answered.

(a) Why were there intra-European differences in the rate of growth of labor productivity? Why did German productivity from 1950-60 grow at 6 per cent (per annum) while the rate of growth of productivity was 4 per cent in France, Italy, Norway, Switzerland, and the Netherlands?

The author claimed that Italian productivity was clearly below that of the other European countries. Since he believes that the level of productivity is negatively related to the long-term growth potential, Italian productivity should have grown at the highest rate. Why did not Italy grow more rapidly than the others, in view of the fact that there was no more deflationary pressure in Italy than in the other countries?

(b) Although the author desires to forecast future growth rates and to distinguish between the long-term and the transitory forces of growth, he has not succeeded in providing an objective basis for his quantitative results.

We have given reasons for thinking that the productivity achievements of some countries, such as Germany, France and Italy, were due to special factors, and have also suggested that the productivity growth potential of European countries is better than that of the United States. To go further than this and pick on a particular rate as a yardstick, of course, involves some guesswork, but, after so much statistical analysis, we should be willing to venture a judgment. For European countries an average productivity growth rate of less than 3 per cent a year can be taken as evidence of deficient policy. . . . For the United States and Canada it is difficult to fix a norm, but by the standards of the early 1950's, their productivity performance from 1955 onwards was very poor.

No European economy achieved a 3 per cent growth rate of labor productivity from 1870-1913 or from 1913-50; and only Sweden reached that rate from 1938-60. Maddison's 3 per cent long-term growth rate was arrived at subjectively, and he admits that it involved guesswork. Nevertheless, he is an ardent advocate of growthmanship: the policy (summarized in number 4 above) of actively managing the economy to see that investment is adequate to achieve a certain target rate of growth. On what grounds can one advocate managing an economy to achieve a capacity growth rate that is founded on guesswork and exceeds all long-term trends? Particular attention should be given to number 3 above: that policy decisions were based upon ignorance of the facts. His policy conclusions are not grounded in a quantitatively objective analysis.

This volume is interesting and useful in two respects. First, it is a serious study of the remarkable growth rates achieved by the Common Market countries relative to the experiences of the United States and the United Kingdom. Second, it demonstrates the need for using a much more sophisticated tool of analysis than the Harrod-Domar identity in explaining this empirical phenomenon.

*Experiments on a Simulated Underdeveloped Economy: Development Plans and Balance-of-Payments Policies.* By EDWARD P. HOLLAND WITH ROBERT W. GILLESPIE. Cambridge: The M.I.T. Press, 1963. Pp. xviii, 289. \$8.00.

As the author states in his preface, this book "is a report on some exploratory experiments in economic dynamics performed on a simulated underdeveloped economy." A 250-equation dynamic model was used to represent the economic structure of a typical underdeveloped society. Data on the economy of India provided a guide to intuition in the selection of the relevant parameter magnitudes. Sensitivity studies were undertaken to investigate the nature of desirable adjustments to two important economic problems facing most underdeveloped nations today: inflation and the maintenance of a satisfactory balance of payments. The merits of alternative development programs, as represented by different levels and sectoral allocations of investment, were then investigated in this context. Finally, several trade policies were studied in a similar manner.

The one major criticism of Dr. Holland's procedure which must be made is that the nature of the compromise between flexibility in dynamic specification and disaggregation within a single time period is not especially appropriate for the investigation of long-run development. On the one hand, a very short time-step—one-twentieth of a year—was used, a choice which permits the relationships in the economy to include many modes of feedback and to vary with time in other ways in as complex a manner as desired. For example, the supply functions were made to shift through time in response to new

investment, changes in prices of intermediate products, and variations in wage rates. Similarly, a kink was built into the short-run supply functions, and a ratchet effect into the wage-rate equations.

On the other hand, even though a simple equation count indicates that the simulation effort was quite detailed, the actual number of behavioral relationships included in the model is in fact rather small (of the order of 30). This means that many compromises in the degree of disaggregation had to be made because of computer time and computer memory limitations, and therefore that the normal economic relationships were treated relatively crudely. Specifically, the productive activities of the economy were aggregated into a mere six sectors, and the effects of income distribution upon consumption patterns, as well as most of the economic manifestations of dualism, were entirely ignored. This set of compromises appears to this reviewer to be much more relevant to the investigation of short-run stabilization in an industrialized society than it is to long-run planning of economic development.

In spite of this shortcoming, Holland's investigation demonstrates forcefully the great potential of simulation techniques in the construction of practical development programs. If a model is chosen which constitutes a reasonable representation of the economic interactions of the real world, simulations of this type offer a promising (and humane!) alternative to direct experimentation with an existing economic system. Simulation, in other words, can be used to estimate the effect of different planning objectives upon the time paths of the important economic variables. Similarly, parametric studies of policy-induced changes in such characteristics of the system as its behavioral propensities, its instrument variables, and the inertia of its institutions can be analyzed before policy decisions are made. It must, of course, be recognized by the analyst that the virtue of the use of computer simulation techniques in this manner is not that one can get accurate predictions of the effects of specific policies, but rather that one can acquire at least a basic understanding of and a qualitative feeling for the reactions of the economy to various events.

The usefulness of the technique depends crucially upon the validity of the representation of the system to be simulated. Unfortunately, it is extremely difficult to determine, before experimenting upon the economy in question, just how appropriate the model employed is to the problem at hand. It is in this area, the construction of suitable tests to determine the degree of correspondence of the computer model to the real economy, that new work and new ideas are especially needed. In his simulation, Holland did not have to face this problem, since he was analyzing a synthetic, albeit realistic, economy. Clearly, however, successful application of simulation techniques to existing economies will require considerable attention to the correspondence between model and country.

*Capital Formation and Investment in Industry—A Report of the International Conference on Problems of Capital Formation and Investment in Industry Held at Istanbul, August 6-25, 1962.* Istanbul: Economic and Social Studies Conference Board, 1963. Pp. xvii, 467.

This volume is the report of a three-week conference held in Istanbul in August, 1962. One week each was devoted to domestic sources of capital and manpower, foreign aid, and planning, as each of these affects the industrialization process. For the most part, the format of the book is a sort of "club sandwich"—a layer of foreign expertise, a layer of Turkish experience, a second layer of foreign expertise, etc. Most of the speakers were economists, but both private enterprise and public administration were also represented.

When one scans a table of contents and sees such names as Bert Hoselitz, Basil Yamey, John Adler, Roy Harrod, Hollis Chenery, Arthur Lewis, Pitambar Pant—and others all distinguished in one way or another—one's appetite is naturally whetted. On the whole, however, the volume is disappointing. The Turkish contributions add up to a useful picture of Turkish problems and policies, but the foreign contributions add up, at best, to a rather dull textbook. There is a general *de haut en bas* flavor about these chapters; the foreigners clearly did not reserve the more brilliant of their recent ideas for this occasion. W. A. Lewis, for example, provides a scant five pages in which he says that agricultural improvement is essential for industrial development. Hollis Chenery, in five and one-half pages, describes foreign aid programs, particularly the U.S. one, and offers a mild criticism of the "project approach" to foreign aid. Some of the other foreign papers were somewhat longer, but few were more original.

There are some bright spots. The reviewer particularly enjoyed the neat demonstration by Professor El. Naggat and Sir Roy Harrod that only a fraction of PL 480 commodity surplus disposal is really "aid," and that recipient countries are usually better off if counterpart funds are not spent at all. Mr. Cihat Iren provides a splendid example of how governments of developing countries discourage foreign investment while passing laws ostensibly designed to encourage it. Readers who have not encountered it elsewhere will find Pitambar Pant's description of perspective planning in India interesting, although some may share the reviewer's feeling that it is slightly curious for an avowedly socialist country to take the Pareto curve as given and use it as the foundation for long-run planning. Sir Roy Harrod's arithmetic on ICOR and assisted take-off is useful, although not altogether new. There are also some very low spots, such as Maxwell Stamp's condemnation of foreign aid as "charity" and his stern rebuke to the peoples of underdeveloped countries for dissipating savings for ceremonial purposes (does he feel the same way about support to opera and ballet, I wonder?).

More interesting to the reviewer than anything clearly said is the thread of between-the-lines bewilderment that runs throughout the volume. There is a general agreement that, in meeting the problems of developing countries, marginal analysis and reliance on free market adjustments alone are not

enough; and there is general discomfiture over the uncertainty as to just what should be put in their place. In this respect, of course, the authors merely reflect the current condition of the economics profession. (The nineteenth-century cohesion of economic and political philosophy is gone.) The volume opens with a foreword by Ismet İnönü, Prime Minister of Turkey. There are only two systems of economic development, he says; Turkey has chosen the "democratic system." But "democracy" is not a system of economic development. It neither guarantees nor prevents development in itself and is consistent with a wide range of ratios of public to total investment, with varying degrees of control over the private sector, and with various types of planning. *Laissez faire* or economic liberalism may be a "system" of economic development, but it is one Turkey has renounced in favor of a mixed and managed economy. Moreover, it is clear from this volume that the Turks are no closer than anyone else to a clearly articulated political philosophy to justify and guide the mixed and managed economy. Indeed, as Osmar Okyar makes clear in his chapter, Turkey has had trouble enough in formulating the economic rules of the game in such a society. Similarly, Professor Ülgener displays the typical uneasiness of the economist who sees a necessity of substituting some shadow prices for some market prices (although he does not use these terms) but does not know exactly how shadow prices should be determined.

Clearest in his own mind on this range of subjects is Sir Roy Harrod. He comes out squarely for perspective planning as well as short-run management and (in sharp contrast to Dr. Willmann) denies any conflict between planning and freedom: "Nobody is compelled to do anything except perhaps the state enterprises. . . . The success depends on a confidence that the different sectors will play the game in their own interest." Nor is the price mechanism inconsistent with planning: "On the contrary, if the price system is working smoothly, it is a sign that the planning itself has been efficient." Harrod also makes the significant distinction between taking savings as given, while planning total investment so as to achieve stated objectives, and treating savings as a policy variable.

The book is, unfortunately, all too typical of recent publications in the field of economic development and reflects the generally low state of the art of development planning. We badly need two things: facts concerning the whole vast array of parameters governing economic development and a new, systematic social philosophy to fit societies which no longer accept the free market as the sole guide to economic policy and the sole mechanism for economic growth, but which have not embraced the Communist faith.

*Hungarian National Income and Product in 1955.* By T. P. ALTON, L. CZIRJAK, L. SMOLINSKY, AND G. PALL. New York and London: Columbia University Press, 1963. Pp. xv, 254. \$5.00.

This study not only provides the necessary material for the analysis and

understanding of the Hungarian economy in the prerevolutionary era but, with its analytical methods, sets an example of how to make a successful estimation of national income in a Soviet-type economy. Moreover, the description and evaluation of Hungary's economy serve to characterize the general pattern of structural changes in the whole East Central European area.

The Soviet-type economies of East Central Europe, with a population 45 per cent that of the Soviet Union, have an output roughly equal to the same proportion of the total USSR production. This represents an important element in the world's economy. Although an increasing amount of economic information is being published by these countries, the concepts in which most of the data are reported, the peculiarities and distortions of the existing price system in which the values are expressed, require a separate analysis. As is well known, official income statistics coming from Soviet-type economies are given in prices which represent the preference of the Central Planning Bureaus, and the price of products will neither reflect their relative scarcities nor represent the real factor costs. Thus the official figures should be modified especially for international comparisons.

The authors in this study recalculate Hungary's national income and its components in terms of their real factor costs. The price of a good or service is re-evaluated on the basis of the real costs of inputs, and, by this method, the price distortions are ironed out. On this basis, the authors represent the national accounts in accordance with standard methodology and concepts of the West, showing the sources and final uses of gross national product. The authors in doing this enormous research (recalculating the real costs of all hired factors and deriving the national income) obviously faced many difficulties, and it is natural, in spite of the very important contribution and material presented in the study, that they were unable to overcome all the pitfalls.

It is known that in the Soviet-type economies the prices of consumer goods tend to deviate considerably from the real factor costs due to higher rates of turnover taxes imposed on such goods. To evaluate an undistorted consumer-good price, the real burden on the households (the aggregate sales tax, turnover tax levy) should be counted. The authors do this, and they claim that the turnover taxes represent 62 per cent of the state revenues (p. 90). This huge sum is the basic source for government services and investments, but it is also probable that these turnover taxes were used for financing the losses that Hungary suffered in foreign trade. However, the study does not indicate clearly the latter use of available government funds. Moreover, it deducts the loss in foreign trade from the national income. This method is completely justified in a Western price-directed economy, but not in a Soviet-type economy where the state firms are compensated in internal prices for their products, whatever may be the prices in the international market.

From this it follows that the Hungarian national income, which is given as around 112 billion in 1955 forints (p. 222), is probably underestimated. This consideration will demand caution of anyone using the results of this study for international comparisons.

The volume also provides the framework for a forthcoming study of Hungary's economic growth in the period 1938-60.

*Large Economic Regions of the U.S.S.R.—Some Problems in Territorial Organization of the Economy.* By L. N. TELEPKO. Moscow: Institute of Economics, Academy of Science, USSR, 1963. Pp. 198. Rbl. 0.53.

The book under review consists of three parts: (1) the regional organization of economy; (2) some problems of specialization of large economic regions; and (3) problems of complex development for large economic regions.

Economic division into districts in the Soviet Union began more than 40 years ago. By the end of 1957 the Soviet Government recognized that the existing departmental branch structure for the management of industry did not meet the requirements for national economic development. In an effort to improve managerial controls over industry, many ministries were abolished and 105 (subsequently reduced to 47) economic-administrative regions were established.

Because of continuing economic problems, the Soviet Union in recent years has undertaken reorganizations in the administration of its industry. In establishing the Councils of National Economy at different administrative levels, it has paid particular attention to the large economic regions. In 1961, 17 large economic regions were established instead of the 13 created at the end of the 1940's.

It is not difficult to determine the chief reasons for these rapid changes. As the Soviet economy became more complex, the problems of its management appeared more difficult. The Soviet Government sincerely believed that all shortcomings, which are in fact an organic part of the Soviet economic system, could be removed by the creation of these regions.

Among the data presented by L. N. Telepko are the predominant specialization of large economic regions in the USSR on the basis of specific weight of industrial branches to all-union production, and major branches of all-union specialization of industry for the 17 large economic regions except Belorussian and Moldavian SSR.

The range of problems considered by the author is wider and includes such questions as: correlation between regional and branch organization of the national economy; territorial division of labor and specialization of economic regions; economic efficiency of the specialization of production and its most important indices; large economic regions and the planning of territorial specialization of production; basic index of the specialization of large economic regions, and some other problems.

It would seem that the author's method of determining the specialization of large economic regions on the basis of the number of workers in the separate branches of industry gives a very inaccurate picture, since he does not take into consideration the differences existing between the branches in terms of

great expenditures required for labor, electric power, mechanization, and the training of labor.

As any book written from a Marxist point of view, this book should be read critically. Once the propaganda is sifted out, however, there remains a considerable volume of interesting and informative material which can be very useful to scholars of the Soviet economic system.

*Mensen en Achtergronden.* By J. G. VAN DILLEN. Groningen: J. B. Wolters, 1964. Pp. 571. Fl. 25.

On the occasion of his 80th birthday a group of colleagues and former students decided to honor Professor J. G. van Dillen of the University of Utrecht with the publication of this volume. It consists of a series of 21 essays by van Dillen himself. Some of these have not been published before, and others are reprints of articles which have retained their importance over the years and are not always easily accessible to interested readers. Van Dillen's scholarly contribution has been a formidable one, and is still expanding. The bibliography of his published writings at the end of the book has over three hundred entries, and we are told that his eagerly awaited, comprehensive work on the economic history of the Dutch Republic in the seventeenth and eighteenth centuries is now in an advanced stage of preparation.

Students of the social sciences who may not already have become familiar with van Dillen's writings will have in the present volume a good opportunity to become acquainted with the range and quality of his work. His time-consuming activities in the archives as editor of source materials on Dutch social and economic history, such as on the Amsterdam Wisselbank and the Amsterdam guilds, had long since earned him among specialists a reputation for meticulous scholarship. As principal editor of the *Tijdschrift voor Geschiedenis* over a period of 40 years, his interests ranged widely beyond the narrow limits of regional specialization, and this breadth of scholarship is also reflected in the selections that have been made for the volume under review. They are grouped under three general headings, namely, (1) nine articles of general interest, (2) five articles on the Russian revolution, and (3) seven articles on the economic and social history of Amsterdam.

In a short review of a publication such as this one, it is a problem to decide what to select for emphasis. Certainly the three articles on the history of the Amsterdam Wisselbank from 1609 to 1820 are a valuable addition to our knowledge of this institution. Only the first of these three articles has hitherto been printed. Together they give us the first authoritative, connected account by the foremost student of the subject of the vicissitudes of the Amsterdam bank from its beginning to its demise. In the article on the size and composition of Amsterdam's population in the seventeenth and eighteenth centuries, his analysis is notable not only for its skill in handling the imperfect source materials, but also for its substantive demonstration that the population of Amsterdam was steadily rebuilt and reinforced in these centuries by people from the surrounding Dutch countryside as well as by massive influxes from

the Southern Netherlands, France, Germany, and Scandinavia and from areas as distant as the Levant and Portugal.

It is likely that the interest of economists, sociologists, and historians will tend to concentrate itself on what Professor van Dillen has to say on broad and general subjects, such as the economic interpretation of imperialism, the significance of the concept of mercantilism in contemporary economic and political thought, the gild system, the relation of economic history to economic theory and sociology, or his discussion of the relative importance of economic and psychological factors in the economic development and stagnation of nations, and the suggestive historical parallels in the economic changes of the Netherlands and England during the last few centuries. The over-all impression conveyed by his discussion of these general topics, as well as by his contributions to regional economic history, underlines once more that contemporary Dutch scholarship in economic history reflects a more thorough utilization and understanding of foreign contributions in this field than can be said to be the case the other way around.

*A Priori Information and Time Series Analysis: Essays in Economic Theory and Measurement.* By FRANKLIN M. FISHER. Contributions to Economic Analysis XXVI. Amsterdam: North-Holland Publishing Co., 1962. Pp. xii, 168. Paper, \$5.00.

Although this book contributes primarily to econometric methodology, the empirical chapters not only illustrate the method, but also include results of interest to students of the wheat, aluminum, and railroad passenger markets. In addition, Franklin Fisher presents a theory of expectation formation, which he tests by experiments with college students and by estimation of the United Kingdom's demand for wheat from 1867 to 1914. Incidentally, this work establishes Fisher as an economic historian and experimental psychologist.

Notwithstanding the term "a priori" in the title, no use is made of formal Bayesian analysis. Instead Fisher, by precept and exhortation, continuously points to the moral that mechanical estimation and hypothesis-testing make little sense in economics and that even apparently simple problems require a mixture of good judgment, statistical knowledge, and economic theory. No doubt some mechanical curve-fitting still goes on in the back rooms of economics departments, so that Fisher's sermon is well taken. Given the nature of computer regression programs, the danger of naïve estimation is ever present, and even the virtuous need to be reminded of this now and then.

In line with the author's prejudice against mechanical procedures, the book starts with a plea for selective estimation. This leads to procedures for grouping together data for certain kinds of years and discarding certain observations. Fisher develops an ingenious method that can estimate both short- and long-term responses based somewhat on his expectations theory.

Fisher develops a novel theory of expectations. According to this theory, crucial information is provided by the turning points of a time series. Briefly, this theory says that firms and households pay particular attention to those turning points that are neither too close together nor too far apart. However, they do not pay attention to the *size* of the change, although the size of their response is assumed to depend on the size of the stimulus.

Fisher does provide a rationale for his expectations and response theory. He argues that it is reasonable to stress turning points of *nonstationary* series. Moreover, since decision-making and the gathering and evaluating of information are costly, it follows that responses are not continuous functions of stimuli and that changes of expectations are not continuous functions of the discrepancy between observations and predictions.

Unfortunately, Fisher's evidence in support of his expectations model is, in his own words, "mild" since it depends on the way that college students forecast the U.K. wheat price series. Moreover, although Fisher cites E. J. Working's expectations model and the Koyck adjustment model, he does not test how well these compare with his own method of estimating long- and short-term responses. The Cagan expectations model used successfully by Friedman, Nerlove, Meiselman, and others provides an alternative to Fisher. It is now known that there is a sound statistical theory for the Cagan model, which had been developed much earlier by Weiner, Wold, and Kolmogorov. For a well-specified class of time series, it can be shown that Cagan's formulation provides good predictions in the least-squares sense, and some writers have developed a theory of rational expectations to exploit these properties. It would be desirable to compare these models with Fisher's expectations theory to see which gives better predictions of behavior. For instance, Fisher summarily rejects the Koyck model without presenting any evidence for doing so.

Two chapters in the book, "The Demand for Aluminum" and "The Demand for Railroad Passenger Traffic," are well worth assignment to advanced undergraduates and beginning graduates. There is an example in the former of Fisher's occasionally cryptic style. Without explanation Fisher deflates the aluminum price by the average metal's price instead of a general price index. It is a tricky exercise for the reader to show why this may avoid biasing downward the estimates of the aluminum price elasticity (see p. 99). The passenger-traffic chapter includes an intricate argument for buttressing Fisher's estimates of the long-run effects of changes in the stock of cars on rail passenger traffic. Fisher supposes that a decrease in the stock of cars is associated with a decrease in rail passenger traffic if it results from a decrease in real income which occurred from 1929-34. However, a rise in the stock of cars also reduces passenger traffic because the two are substitutes. Despite the fact that the basic regression contains an income variable, and despite a paucity of observations that prevents direct tests, Fisher makes out an ingenious, but not entirely convincing, case in support of his hypothesis.

On every page this book displays the brilliance and virtuosity of its author. The arguments are complicated but essentially nonmathematical. Nev-

ertheless, a close reading is rewarding, and attempts by the reader to supply the gaps in the argument will pay handsomely. So much is packed into this book, which is derived from Fisher's Ph.D. dissertation, that a brief review cannot do it justice. The econometrician must read this book; the general economist should at least skim it.

*Essays on the Structure of Social Science Models.* By ALBERT ANDO, FRANKLIN M. FISHER, AND HERBERT A. SIMON. Cambridge: The M.I.T. Press, 1963. Pp. iv, 172. \$5.00.

The most prestigious and perhaps the most prevalent type of current econometric activity appears to involve estimating parameters of models in which the variables are interdependent, so that simultaneous estimation is in principle required, but in which the restraints on the model are sufficient to identify the coefficients, and in many cases to overidentify them. This practice has been attacked on the one hand by Herman Wold, who maintains that in economic reality the underlying cause must precede the effect, whatever may be the case for the observations taken as proxies for the underlying variables, and that therefore any faithful representation of the underlying reality must be in terms of causal chains in which interdependence is absent and elaborate simultaneous estimation procedures are uncalled for. From the other side, T. C. Liu has asserted that all observable variables are inherently interdependent, if not directly, then through pervasive or indirect relations too diverse to be fully represented in any model, so that any attempt at identification of parameters in a specific model by a priori restrictions on some subset of the parameters is necessarily erroneous, and even a separation of variables into exogenous and endogenous is of dubious validity. This collection of essays attempts, among other objectives, to rehabilitate the prevailing practice by examining the mathematical properties of systems in which the specifications are "almost" satisfied.

The general procedure running through these essays is to show that under appropriate conditions the behavior of a system having specified coefficients exactly equal to zero is approached asymptotically by the behavior of sequences of systems for which the corresponding coefficients merely approach zero asymptotically. Three types of systems are discussed: general identified or overidentified systems, block-diagonal or "completely decomposable" systems with nonzero coefficients restricted to square blocks along the diagonal, and block-triangular or "decomposable" systems in which the nonzero coefficients may appear in the square blocks along the diagonal and anywhere above the diagonal. In each case it is shown that when the characteristics of the model are estimated by assuming that the restricted coefficients are all exactly zero when in fact they are nonzero but small, the errors thus made approach zero as the actual coefficients are made to approach zero, provided some reasonably general conditions are met. The demonstration is not trivial, since counterexamples exist where the convergence fails; unfortunately it

does not appear easy to give a nontechnical description of the conditions under which convergence is assured. However, the general tenor of the results is to offer some reassurance to those who, while recognizing that certain coefficients in their models cannot be exactly zero in actuality, nevertheless from convenience or necessity proceed on the assumption that they are exactly zero.

Matrices that are "almost block diagonal," in the sense that the coefficients outside the blocks are small, have a bearing on the aggregation of the variables within the blocks. An important distinction is made between aggregation for short-term analysis and for long-term analysis. In the long run, the variables within each block of a nearly block-diagonal system tend to move proportionately, so that each such set of variables can be represented by an index with good results. In the short run, each block tends to behave as a separate system relatively little affected by development within other blocks. This would seem to be almost reversing the traditional division of labor in which microeconomics is concerned with allocative efficiency in the long run, while macroeconomics is concerned with cyclical phenomena in the short run. If I understand the implications correctly, this type of result will be cold comfort to the analyst who is under pressure to produce short-term results from highly aggregated variables.

Indeed a disturbing feature of the dynamic models under discussion, which comes out especially in the last two essays, is that the convergence upon which so much depends often occurs only in a long run, as to the length of which we are given no very definite indication. Fascinating and elegant as these models may be as mathematical exercises, one has an uneasy feeling that, in a long run long enough for a satisfactory degree of approximation to the required proportionality to be achieved, technological change will have produced fundamental and significant changes in the basic coefficients, and the mathematical demonstration that all would be well if we could only follow the model long enough may be of little practical avail. Even in the short run, while it is some consolation to be told that in the limit the errors vanish, there is a world of difference between this mathematical property of a system and a practical judgment as to whether, if a small but finite error of specification is made or an aggregative shortcut is taken, the resulting error in the results will be within tolerable limits.

As is perhaps inevitable with this subject matter, these essays are not easy reading, even for fairly good mathematical economists. It is to be hoped that econometricians will not, as a result of hasty reading, relax their vigilance against errors of specification or aggregation, and that growthmen, whether under- or overdeveloped, will not be led to seek turnpikes with renewed assiduity. For those prepared to tackle these essays seriously, it is recommended that they first read the excellent introduction with great care, and then turn next to the nonmathematical description of the results in terms of armament races and voting contained in the article drawn from the *American Political Science Review*. Indeed, only the introduction and the last essay on von Neumann rays had not previously been published.

*Econometric Methods.* By J. JOHNSTON. New York: McGraw-Hill Book Co., 1963. Pp. xiii, 300. \$7.50.

*Econometric Theory.* By ARTHUR S. GOLDBERGER. New York: John Wiley & Sons, 1964. Pp. xi, 399. \$10.95.

These two recently published books are the first of several new econometrics texts which will probably be published over the next few years. They represent the first basically new texts suitable for basic classroom use in econometrics since L. R. Klein's well-known *A Textbook of Econometrics* of a decade ago. They both embody much recent work and both offer systematic coverage to a greater or less extent of most of the major topics usually covered in a good graduate econometrics course. They will both doubtless receive heavy use in such courses.

In an effort to make the material reasonably self-contained, both authors devote a chapter to matrix algebra. Arthur Goldberger, in addition, spends over a hundred pages on the elements (and more) of statistical inference, whereas J. Johnston assumes some familiarity with the basic notions and introduces more difficult material when and if needed. While the desire for self-containment is quite understandable and, to some extent, laudable, Goldberger seems to me to have heavily overdone it in this respect. No student without a previous course in statistics will be able to acquire the necessary material from Goldberger alone without a great deal of difficulty, and there are far more suitable texts for statistics-teaching. Goldberger's treatment (as throughout his book) is rigorous without being particularly clear or—in this part—always particularly motivated. To some extent, the same is true of his treatment of matrices. Such chapters in econometrics texts can usefully serve as a convenient summary of results already known to the student or can usefully present those variations on basic results which will be needed, although these can be incorporated in the main text as required. In essentially attempting to provide entire courses in matrices and mathematical statistics, Goldberger goes beyond such useful and perhaps necessary functions to an extent that is likely to weary the average student before he ever gets to the econometrics sections of the book.

As for those sections, which after all are the ones which really count in an econometrics text, the difference in the titles of the two books well describes the basic difference in approach. While roughly the same subjects are covered in both volumes, Goldberger's treatment is heavily theoretical, while Johnston, who does not neglect theory by any means, is largely concerned to convey a feeling for the techniques as used in practice. As a result, Johnston is likely to prove a rather more satisfactory textbook for training students in the techniques of empirical econometric research, even though Goldberger may have more for that minority of students whose basic interest is the theory as opposed to the practice of econometrics. A student trained on Johnston should be able to do good empirical research, while one trained on Goldberger will be somewhat better able to cope with the theoretical literature if he has fully digested Goldberger's not always easy but certainly rigorous treatment. I should hesitate, however, to turn the latter student loose on an empirical project.

As stated, both books cover roughly the same areas and treat most of those topics which would generally be covered in a basic course. Such coverage, however, is by no means complete,<sup>1</sup> and the two works differ greatly in the amount of attention paid to subtopics within the main headings. Thus, for example, neither author adequately discusses such topics as aggregation or specification error to any extent, although one would have thought that some discussion of these would be appropriate. Johnston devotes an entire chapter to the problem of autocorrelated disturbances, while Goldberger gives that topic only very formal treatment as one way in which the classical assumptions of least squares can be violated.

The latter difference leads to another. In treating regressions with lagged dependent variables, Johnston is careful to point out the major problems that arise when lagged variables appear on the right-hand side of a regression and the disturbances are autocorrelated. Goldberger mentions that problem in the context of a particular distributed-lag model, but fails to generalize the point. He also assumes that the Koyck transformation leads to autocorrelated disturbances without pointing out that such a result depends on the autocorrelation properties of the disturbances of the original model. Johnston does point this out, but neither author suggests that in some versions of the model (Nerlove's adjustment model) the "natural" zero autocorrelation assumption is in fact on the disturbances after the Koyck transform. Whether the transformed disturbances are autocorrelated does not depend on the way the model is written; yet both authors write the model before the Koyck transformation and indicate that autocorrelation is probably introduced by that transformation. Incidentally, neither author points out that the Durbin-Watson test is inapplicable in the presence of lagged dependent variables among the regressors.

Turning to a different example of difference in coverage, Johnston gives a somewhat more lengthy discussion of multicollinearity than does Goldberger. The latter, however, gives an elegant treatment of the use of extraneous estimators, a closely related problem only mentioned in Johnston. Unfortunately, Goldberger fails even to mention the difficulties of specification and interpretation that arise in practice when combining different types of data, which problems have been discussed by several authors in the literature. Johnston at least adverts to such problems but also gives no discussion of them.

Such failure adequately to signal the reader that there is danger in incautious application turns up elsewhere in Goldberger. He spends two pages discussing stepwise regression—the practice of regressing residuals from a fitted regression on a new variable to see if it should be included. While he displays the formulae which give the relation between the true coefficients and the ones so estimated, he fails to point out specifically the clear implication that the practice involved is not generally a good one. The space spent on the topic

<sup>1</sup>Both books are dominated in this and other respects by E. Malinvaud's recently published magnificent work, *Méthodes Statistiques de l'Econométrie* (Paris: Dunod, 1964), which is not yet available in an English translation.

and the reference to stepwise regression as a "common practice" are likely to mislead all but the very careful reader in this respect.

Turning to another area, neither author's treatment of identification seems fully satisfactory, although here again Johnston's discussion seems better than Goldberger's. Both authors state the rank condition for identifiability in terms of the rank of a particular submatrix of reduced form coefficients—that corresponding to the included endogenous and excluded exogenous variables. While it is easy to see why the condition in this form is necessary and sufficient for the obtaining of estimates by indirect least squares or one of the other usual methods, it is both clumsy to work with and difficult to interpret. In particular, it bears no intuitive relation to the discussion of the identification problem in terms of admissible linear transformations of the original structure which the student probably finds easy to understand (and which is given by Goldberger but not by Johnston). The classical form of the rank condition in terms directly of the structural parameters, on the other hand, is easy to work with and to interpret, as well as being readily generalizable to cases other than those of exclusion restrictions. That form is given by Johnston but not by Goldberger. Even Johnston, however, adds no intuitive discussion, but presents the classical form for reasons of convenience of handling.

In their treatment of simultaneous equation estimation itself, both books are rather good. Johnston presents a very valuable detailed summary of the Monte Carlo literature, while Goldberger (who also discusses that literature at less length) presents a good discussion of economy-wide models and the implications of dynamic structure. I would disagree, however, with his statement (p. 369) that "economic hypotheses often refer to reduced-form, rather than structural, coefficients. . . ." Hypotheses almost invariably refer to structural coefficients; it is the implications of those hypotheses for policy which refer to the reduced form and which justify Goldberger's discussion.

While both authors appropriately devote considerable space to simultaneous equations, that subject plays a more important role in Goldberger than in Johnston. This doubtless reflects a difference in reasonable men's opinions as to the relative importance of various subjects, yet one wishes that Goldberger had given the same extended treatment to many of the single-equation problems which he discusses at less length than does Johnston.

In general, perhaps no teacher of econometrics is ever fully satisfied with another's treatment. Of the textbooks now available, that by Malinvaud, cited above, seems to me to be entirely the best in terms of completeness of coverage and depth of understanding and discussion. Of the books available in English, however, Johnston's is clearly the most satisfactory for classroom work. Its quality is well above that of the average text, and it provides a useful base for econometrics courses. Such deficiencies as it possesses are easily made up in lectures.

I cannot say as much for Goldberger's book. There are several places in which Goldberger's treatment will provide a valuable adjunct to another text, particularly for advanced students. As a basic text for an econometrics course, however, it seems to me to be too lacking in clarity, ease of presentation, and

intuitive discussion to be really satisfactory in a course in which a major objective is the training of students in the techniques of empirical research.

*Soviet Strategy for Economic Growth.* By NICOLAS SPULBER. Bloomington: Indiana University Press, 1964. Pp. 175. \$4.50.

*Foundations of Soviet Strategy for Economic Growth—Selected Soviet Essays, 1924-1930.* Edited by NICOLAS SPULBER. Bloomington: Indiana University Press, 1964. Pp. xii, 530. \$12.50; both volumes, \$15.00.

The 1920's were a golden age in Soviet history. Following the successful defense of the Revolution against civil war and foreign intervention, Russia entered upon the years of the New Economic Policy, an exhilarating period of reconstruction and change, fraught with hope for the new world in the making. In contrast to the totalitarian age that would shortly stifle Russia under a ruthless Stalin, it was a time of great freedom. Though political liberties were severely circumscribed, there nonetheless was open and intense discussion, both inside and outside the Communist Party, of the myriad issues facing the new state. Among these, none attracted so much attention nor drew into the lists such a star-studded cast of debaters as industrialization and planning. For while most everyone agreed that industrialization was essential for the security of Russian socialism, there was very little agreement about what planning entailed and what role it should perform in achieving industrialization. This was hardly surprising, for in the 1920's Russia was pioneering new forms of economic institutions, and the guideposts to be followed were not self-evident. Some sought these in the hallowed pages of *Capital*, others in bourgeois economic analysis, and still others in the principles of engineering. And always there to remind Marxists, economists, and engineers alike of the urgency of the issues were the Party leaders—Trotsky, Stalin, and Bukharin, to name the most prominent—who themselves participated in the discussion and so made it part of the bitter struggle for the succession of Lenin.

The debate thus generated stands with the greatest in the history of economics. There was, in the first place, something to debate about. A crisis confronted the Soviet economy. In the latter part of the 1920's the perennial Russian agricultural problem was exacerbated as the terms of trade moved against the peasant, prompting him to reduce the goods he exchanged for manufactured output. The revolutionary chickens had come home to roost. For in the institutional changes brought about by the Bolsheviks, the peasants had acquired greater freedom in the disposal of their crops. At the same time the recovery of industrial output during the New Economic Policy was achieved at the cost of the depreciation of the capital stock inherited from the Tsarist regime. Now the period of socialist reconstruction was at hand. With the source of accumulation declining even as the needs of the economy

for net investment were expanding, how was the bill for industrialization to be paid? In the second place, while seeking planning and socialist solutions to these problems, the Russians debated issues of wide general interest and in fact anticipated many that have subsequently come to absorb the attention of Western economists. Here one finds discussions of input-output analysis, national income accounting, investment efficiency, growth models, sectoral priorities in development, balanced versus unbalanced growth. Had not Stalin choked off the debate in the purges and repressions of the 1930's, it is not unreasonable to conjecture that Russia might have established itself at the forefront of the economics of growth and development. But in the event the opportunity passed, and Soviet economics succumbed to a dreary litany of Marxian platitudes.

In view of the fact that these early concerns of Soviet economics have become central to much contemporary work in Western economics, it is surprising that so little attention has been paid to them in the Anglo-American world. Aside from contributions by Maurice Dobb, Evsey Domar, and especially Alexander Erlich, there is little to go by. The two volumes under review, therefore, are all the more welcome. Professor Spulber has written a long essay on the issues in the debate and the positions taken by the *dramatis personae* which can serve as an introduction and guide to a companion volume of translated papers drawn from economic sources—journals, reports, books—published in Russia at the time. Now for the first time the English reader can witness the debate from the inside.

It should be said at once that the debate thus seen is not always easy going. The papers are occasionally dull, sometimes pompous ("But to the mathematical logic of the S-curve, the proletariat has opposed the dialectical logic of socialist growth" [*Foundations* . . . , p. 303]), and too often polemical. But these are shortcomings that Western economists can hardly disclaim. More difficult is the Marxian medium in which much of the debate is conducted. Not only do the reproduction tables in the second volume of *Capital* serve as the point of departure for the discussions of growth, but the papers are laced throughout with the jargon of Marxian economics. Fortunately for those economists whose knowledge of Marx is rusty, Spulber's excellent essay is ready at hand. Here in familiar idiom one may first become acquainted with the economic problems confronting the Soviet Union in the 1920's and the various solutions suggested by the participants in the debate.

The translated papers are grouped under four sections (Macro-Economic Models; Economic Growth: Strategies of Development; Economic Growth: Pace and Efficiency; and Planning Theories and Methods) and in each one readers will find selections of exceptional interest. This reviewer found particularly stimulating the contributions of E. A. Preobrazhenski, a member of the left opposition and a strong advocate of forced industrialization; V. Bazarov, a general-equilibrium critic of so-called teleological planning; and N. D. Kondrat'ev, a supporter of growth through agricultural development. Economists who like to play with growth models will find much substance in the papers of G. A. Fel'dman. Also of more than passing interest is a short

critical note by W. Leontief on "The Balance of the Economy of the USSR" (first published in *Planovoe khoziaistvo* in 1925). N. I. Bukharin and J. Stalin are represented, and though their pieces are polemical, they are an appropriate reminder of the rugged political milieu in which the debate was carried on.

One over-all impression strikes the reader of these papers forcibly: none of the contributors (Stalin's paper was dated November 24, 1928) anticipated the drastic changes that were shortly to take place in Russia with the collectivization of agriculture. Whatever their view of planning, however much they thought the pace of industrialization could or could not be hastened, they assumed that socialist society in Russia should maximize consumer satisfaction over the coming 10-15 year period. Because this premise was widely accepted, there could be a fruitful dialogue. By the same token, however, it lends an air of unreality to the proceedings simply because we view them from the present day with the full knowledge that Stalin made capital accumulation a domineering end seemingly unrelated to consumption. Yet the economic issues themselves are universal and indeed are being debated today the world around. Spulber is to be congratulated for giving wider currency to the Russian contribution to the discussion of these issues.

*Contemporary Economic Systems—A Comparative Analysis.* By CARL LANDAUER. Philadelphia and New York: J. B. Lippincott Co., 1964. Pp. x, 560. \$8.95; text, \$7.00.

The object of comparative economics is to study the *modus operandi* of contemporary economic systems, i.e., the ways in which they solve the problems of how, what, and for whom to produce, and to show how these systems interact, i.e., in which ways their differences lead to conflicts or to mutual accommodations.

Unfortunately, many of the available textbooks tend to dwell at length on the *modus operandi* of capitalism in a sort of sanitized, purely competitive setting and fail to point out how, when, why, and in which ways diversity arises under capitalism. Further, some authors tend to classify systems by the main instrument they use, e.g., reliance or nonreliance on the market for key decision-making, rather than by the form of ownership on which each system rests and which determines its respective dominant drive, e.g., the profit motive under capitalism. Others stress—and this reviewer inclines toward this school—that the differences among systems arise from the predominant form of ownership prevailing in them and the drive it generates, while differences within each system arise under a variety of impacts from the ways in which the instrumentalities—market mechanisms or planning and administrative devices—are combined with one another. But, since there is no consensus on definitions, many textbooks tend to be obscure on these crucial points, or worse, tend to change criteria from one chapter to the next. Finally, while the economics of free enterprise is presented within the simplified

standard frame suitable for instruction in economics, in which historical or geographical material need not be called in to the rescue, the economics of communism is usually presented in the historical perspective of the Soviet Union's economic evolution. The tendency to identify any system with its preferential instruments rather than with the forms of ownership on which it rests, and the pursuit of analysis on different theoretical planes, leads to a static and disjointed analysis, in which the systems analyzed are presented in an orderly fashion like cake layers, each of a different substance and of a different consistency. But one can hardly visualize in all this either the patterns of convergence of these systems or the ways in which these systems interact. The main object of the whole effort is thus somehow lost in the process.

In terms of space devoted to each system, Professor Landauer attempts to strike a fair balance: to capitalism, identified by him with the U.S. economy in its changing aspects, he devotes 135 pages, and to communism, centered on the USSR and Yugoslavia's evolution, he allots some 170 pages. Capitalism is defined primarily as a system of "relatively unrestricted rights of private property"; Soviet-type communism, as a system of primarily collective ownership. Between the two systems, Landauer places an 85-page section which he calls "socialism." The latter is identified by him, though not quite explicitly, by a sort of capitalism in which nationalized or cooperative enterprises are established in a more or less extensive way. "Socialism" is further deemed to be closely associated with tendencies toward planning and welfare policies. These definitions cover roughly, but not exactly, what the French usually call "capitalisme dirigé," that is, guided capitalism, or "étatisme," that is, broad state interventions in the management of the economy as a whole. Landauer ranges in his "socialist" section from Great Britain for both expansion of state-owned enterprises and of government control over them during the Labour government to present-day France more for its planning than for the extent of its nationalizations, to Sweden primarily for its cooperatives and its welfare policies, and then to Israel for its *kibbutz* collective agriculture. Landauer's "socialism" is situated in a sort of limbo: it is not clearly included under capitalism and not truly related to the Soviet Union's communism, as the latter is characterized by comprehensive public ownership and by nonreliance on market signals. One wonders why socialism so defined includes only developed countries: it could just as well apply to Mexico, or Turkey, India, or the U.A.R., Ghana or many others—some of which are placed by Landauer for not very compelling reasons into a short section appended after "Communism" titled "Primitive and Underdeveloped Areas." This separate "socialist" section obscures rather than illuminates the wide capitalist and communist spectra. Further, the treatment of capitalism and communism is pursued on different planes, with the Soviet and Yugoslav communisms treated in historical perspective, with the usual negative results as previously mentioned.

From the outset Landauer rightly stresses that, as far as instrumentalities are concerned, all systems are reducible to the same components: all coordinate economic activity by command and/or by exchange; all are laced by

ties of solidarity and self-interest; all are tinted in various ways by traditions and customs. As in architecture, there are many differences among systems in style and design but little variety from brick to brick. Actually certain combinations of basic building stuffs can be erected on the soil of either a predominantly private or predominantly collectivized economy.

Currently the Soviet-type economies tend toward diversifying their "brick arrangements." With respect to the management of state property, there is a variety of tendencies toward decentralization. Regarding planning strategy and procedure, there are many tendencies toward wider utilization of market mechanisms and rationalization of prices. Concerning technological options, there are strong departures from the traditional Soviet models. While in respect to property relations the capitalist and the Soviet-type communist economies remain very different, in terms of instrumentalities they tend often toward convergent solutions. The same types of problems appear, and roughly the same types of solutions are envisaged and implemented in both systems. On this basis, Landauer suggests that capitalism and communism "will eventually meet under the sign of socialism—provided the present tendencies are not stopped or reversed before the meeting takes place" (p. 537). This reviewer feels that the two evolutions often take place along parallel lines, but two such structurally diverse species will continue to remain entirely apart, though they tend to develop similar "protective" adjustments to a changing environment.

Although I differ with Landauer's structural emphasis, there can be no question concerning his handling of the basic concepts which he presents with precision and authority.

*Pricing and Employment in the Trade Cycle—A Study of British Manufacturing Industry, 1950-61.* By R. R. NEILD. National Institute of Economic and Social Research Occasional Paper 21. New York: Cambridge University Press, 1963. Pp. viii, 73. \$3.00.

Robert Neild has produced a compact, high-quality econometric study on the cyclical determinants of prices, profits, and employment in the manufacturing sector of the United Kingdom. He presents a short comparison of U.K. and U.S. cyclical profit behavior. The least-squares price equations are consistent with the view that prices are fundamentally a markup on long-run unit labor and material costs. Prices do not respond to short-run variations in unit labor costs as they do to long-run trend movements. A measure of demand pressures turns out to be statistically insignificant. While this result could, as usual, arise from data imperfections, reaffirmation of the overwhelmingly cost-oriented response of price surely reflects strong elements of non-competitiveness in manufacturing.

Once strong statistical support had been found for a theory based on long-

run price decisions, however, the dynamic response of prices to wage and raw-material costs (for which U.K. indexes appear distinctly superior to those for the U.S.) is similar: two quarters after either cost change, prices have increased by about seven-tenths of their total response. Long-run implications for profits are not immediately obvious, although parameter estimates imply that an increase in unit labor and unit material costs will be reflected in an equiproportional increase in prices, suggesting a price policy consistent with the constancy of long-run factor shares.

The labor-employment relations for manufacturing provide further illumination about the short-run determinants of labor productivity, a matter of genuine importance, because:

If in a recession productivity falls below the trend level, profits per unit will be squeezed. How far this will happen will depend on the extent to which firms adjust employment and working hours when output changes. If, as an extreme example, employment and hours are not changed at all, output per man will change in proportion to output; labour will be in the nature of an overhead cost. In that event, labour incomes will be constant and an initial fluctuation in demand (say, in exports) will lead simply to a change in profits. Since short run variations in profits are reflected mainly in changes in company savings and in tax payments, the effect on consumer spending will be small: the multiplier will be low. If, on the other hand, firms quickly adjust employment and hours, an initial movement in demand will impinge more strongly on labour incomes and less on profit margins: the multiplier will be higher. Thus the extent to which employers adjust their employment and hours governs the value of the short run multiplier (pp. 28-29).

Generally speaking, theoretical implications and statistical quality of the employment and man-hour demand equations, as a function of lagged outputs and trend, are quite different. The explained fraction of variance of the quarter-to-quarter change is .74 for employment and only .60 for man-hours. The impact of output in the man-hours equation is more heavily concentrated in the current period than in the employment equation since hours are more rapidly adjusted than employment. A disquieting implication of these estimates, recognized by Neild, is that the long-run employment increase is only about one-third to two-fifths per cent in response to a maintained 1 per cent increase in output according to the preferred sets of estimated parameters. This seems much too low if similar analyses of U.S. manufacturing have the slightest relevance. The implied extent of increasing returns to scale (a scale factor between two and three for a homogeneous function) appears implausible. Explicit recognition of the distinction between the dynamic employment response of production and nonproduction workers ought to improve conformity to theoretically more acceptable parameters.

Neild compares the cyclical sensitivity of profits in the United Kingdom and the United States. He concludes that the sharper cyclical variations in U.S. gross corporate profits (measured as deviations from trend) are more closely related to price-flexibility than to labor-productivity variations, be-

cause the United States had larger per cent deviations from trend in profits and smaller variations in productivity than in the United Kingdom. "In the [U.S.] downswing there is usually some temporary decline in output per man-hour because manhours are not cut quite as fast as output. But by the time the trough in output is reached, manhours have generally been reduced in almost the same proportion as output . . ." (p. 46). These inferences are open to question. First, the "temporary decline" in productivity during periods of rapid output decline often is substantial, as columns (3)-(4) of the table indicate. These quarter-to-quarter calculations relating to profit and productivity provide more powerful evidence than the annual profit data used by Neild. His choice of peak-trough comparisons obscures characteristic profit-productivity relations since slight changes in the end points make a drastic difference in the reported comparisons, as careful examination of the table reveals. The cogency of these observations cannot be fully established until an analogous treatment of British data is available.

Second, Neild estimates all variations in hours worked from the one available series, that for production workers. While nonproduction-worker-hours are not available on a convenient basis, a more defensible assumption is that nonproduction employees work a constant 40 hours per week. Thus the total drop in hours has been overestimated, which makes a modest difference, as reported in columns (2) and (4) of the table. Since comparable U.K. nonproduction labor is only slightly less, differential U.K.-U.S. behavior would be only slightly affected by this adjustment.

The main purpose of this study, to improve national income forecasting procedures, has been well served. Of more lasting value, however, are the quantitative and qualitative insights into the short-run dynamics of an advanced industrial economy.

*American Growth and the Balance of Payments 1820-1913—A Study of the Long Swing.* By JEFFREY G. WILLIAMSON. Chapel Hill: University of North Carolina Press, 1964. Pp. xviii, 298. \$7.50.

The increased willingness of economists to accept the view that long swings or Kuznets cycles did exist in the nineteenth-century U.S. domestic economy has raised the question whether such long swings also existed in the foreign sector? Were the flows of people, commodities, securities, and gold across U.S. borders also subject to long swings, and were these swings dominated by the U.S. economy or by economic fluctuations in other parts of the world, particularly in the United Kingdom? A decade ago Brinley Thomas examined the relationship of the long swing and the flow of European migrants to the United States. Jeffrey Williamson, using data relating to nineteenth-century U.S. foreign trade and capital flows developed by North, Simon, and others has now extended this investigation to the existence and source of long swings in the flow of commodities, net capital, and gold over the period 1820-1913. Williamson finds that the major items in the balance of payments were subject to long swings; long swings in domestic development were the principal

cause of the fluctuations in the trade balance and net capital flows; the flow of specie acted only to complete the real transfer already initiated; and the Kuznets cycle in the United Kingdom, insofar as it is identifiable, likely had its source in the United States.

Although nineteenth-century data relating to price changes, gold flows, and net capital flows have their limitations, and despite the adjustments needed to isolate the long swing, Williamson offers a convincing case for the existence of Kuznets cycles in imports and net capital flows through most of the century and the idea that these fluctuations were related to the domestic Kuznets cycle as represented by transport-building, construction, and other indexes of industrial output. Since the long-run state of the balance of payments depended on the growth of U.S. output along with the rates of return on capital and changes in the price level in Europe and the United States, given the structure of comparative advantage in the United States and Europe up to the 1890's, one is not surprised to find that such a relationship existed. What is less certain, despite the regression-analysis presented here, is the lag of imports and net capital inflows behind domestic activity, especially at the lower turning point. The evidence seems to support the independence of the U.S. swing, but it is not overwhelming. For an earlier period, the impact of the American colonies on the upswing in British economy activity in the period 1740-60 has yet to be settled. For the period 1820-60, Williamson's analysis adds little to North's explanation of Anglo-American economic relations, and the comments of Hughes and Rosenberg still hold good (see *The Economic History Review*, Vol. XV, No. 3, April 1963). Finally, the timing of net capital exports from Great Britain, the most obvious evidence of the Kuznets cycle, requires a more detailed analysis of the existence of long swings in other countries if the source of the British swing after 1860 is to be found in the United States.

The major shortcoming of Williamson's thesis is his exclusion of short-term capital flows, particularly as these are influenced by long swings in domestic output. It is unlikely that a satisfactory explanation of the long swing will be found without a detailed study of short-term capital flows within the whole Atlantic economy. Such a study might indicate that short-term capital flows financed the flow of imports into the United States in the initial stages of the upswing and that long-term capital exports from Great Britain did not take place until later. Under these circumstances British exports of capital to the United States to a substantial extent would be independent of U.S. transport development, though not of the long-term growth of U.S. exports. Williamson's limited statistical test of the U.S. "pull" and the British "push" as they affected capital flows over the period 1871-1914 tends to support this view. The imperfect knowledge available to the British saver, who was essentially averse to risk, produced a lagged recognition of the profitability of U.S. transportation investment both in the upswing and the downswing. The long-term growth of exports, which did not undergo long swings after 1845, enabled hope to spring eternal in the hearts of disappointed British investors. The consequences of such behavior for a capital-stock adjustment theory of the long swing are evident.

What then can be said about Williamson's contention that the concept of the long cycle is useful not only for analysis of the historical past but for the formulation of current economic policy, since the author implies that, if the United States followed a policy of achieving rapid growth and full employment, the balance of payments problem would tend to disappear in the long run? Some support for this thesis can be found in the Report of the Royal Commission on Banking and Finance recently issued in Canada. The Commissioners seem to endorse the usefulness of the long cycle as a guide to economic analysis and policy formulation within the Canadian economy and imply that a high level of economic growth has tended to ease Canada's balance of payments problem for much the same reasons as those outlined by Williamson.

It is evident that the experience of the Canadian economy in the postwar period, while tending to support an explanation of U.S. economic behavior in the nineteenth century, may be of little relevance to the United States today. However, it is significant that the Commissioners also failed to integrate adequately the long-run and short-run aspects of economic growth. When the United States was on the gold standard in the nineteenth century, Williamson finds a positive correlation between the rate of economic development and the rate of gold flow. Periods of rapid economic growth were characterized by net capital inflows that not only permitted maximum growth to continue over long periods of time but added to domestic growth by supplying a widening basis for the expansion of liquidity in the upswing. How far the movements of short-term capital contributed to this adjustment and the extent to which such movements were a function of domestic economic growth remain unexplained. Whatever may be the case for the twentieth century, the analysis of nineteenth-century short-term capital flows will not be easy. For example, to track down the short-term capital held by Americans in foreign banks is a task that will challenge the most astute economic detective. He would be well advised, however, to begin his search by reading this excellent guide book.

### **Money, Credit and Banking; Monetary Policy; Consumer Finance; Mortgage Credit**

*Money, Capital, and Prices.* By GEORGE HORWICH. Homewood, Illinois: Richard D. Irwin, Inc., 1964. Pp. xiv, 556. \$12.50.

Professor Horwich's volume is the first in a new monograph series sponsored by Purdue's Krannert Graduate School of Industrial Administration and Richard D. Irwin, Inc. According to the publisher, additional volumes in the series are anticipated which will report on experimental studies of economic behavior, econometric studies of the American economy, new managerial and production techniques, and studies of economic development.

The first volume sets a very high standard for those which are to follow. It

is not a book to be merely read, however. Instead, it needs to be studied most carefully, and then restudied, for one to be at all reasonably sure of achieving full comprehension of the author's argument and its implications.

Let us not fault Horwich for this, though, but view it as the inevitable result of his having worked his analysis out most carefully and elaborately and at a very high level of abstraction. Also, he is dealing with a complicated subject that simply does not lend itself to treatment in an uncomplicated way. Thus, as he notes:

. . . the analysis is highly aggregative and contains little more than the minimum number of variables needed for a complete stock-flow system. But even this number creates an analytical network whose inter-relationships are sometimes both numerous and complex.

The volume has been long in preparation (Horwich indicates that it had its beginnings in his doctoral dissertation, submitted in 1954). What has finally emerged is a closely reasoned and very detailed description of, first, the impact of externally induced monetary change on an aggregative model of a closed economy; and, second, the resultant process of adjustment within the model to the monetary "disturbances" introduced. Throughout, the theoretical methodology employed is that of general equilibrium analysis.

All this is contained in ten lengthy chapters, accompanied by seven appendices. The first chapter provides an overview of the whole analysis. The second builds the model into and within which, in Chapters 3-6, monetary disturbances (resulting from central bank open-market operations) are introduced, and the adjustment processes flowing from them are depicted and analyzed in great detail. Then, in Chapters 7-9, the preceding detailed analysis is generalized in various ways: by altering the model (e.g., a two-security instead of a one-security model, to create opportunity for viewing monetary disturbances against the backdrop of the interest structure); by assuming *continuous* instead of "once-for-all" open-market operations as the source of monetary disturbance; by assuming other sources of monetary disturbance than open-market operations—*independent shifts in savings and investment, government budgetary deficits and surpluses, independent changes in active velocity, shifts in existing-asset demand, and autonomous movements between idle and active balances; and by introducing a sector of financial intermediaries.*

The concluding chapter provides a restatement and critique of interest and price theory. The writings of Patinkin and Keynes are viewed as providing the major alternatives to the analysis developed by Horwich. But to Horwich, whose very first paragraph stipulates that "In a sense, stock-flow analysis and fidelity to stock-flow relationships of the monetary system are the central themes of this volume," Patinkin's use of the "real-balance effect" blurs, rather than clarifies, stock-flow concepts. Other shortcomings of the "Patinkinian" approach include:

Denial of the medium-of-exchange function of money and the traditional income-expenditures relationship (as a consequence of Patinkin's attack

on the "dichotomy" of the real and monetary sectors, as entailing an indeterminate price level); and

Disregard of the store-of-value function of money (as a consequence of Patinkin's claim that a system in which saving and investment are exclusively a demand for and supply of securities also has an indeterminate price level).

Keynes and, among his latter-day interpreters, Lloyd Metzler fare no better than Patinkin at Horwich's hands. The liquidity-preference propositions bear the brunt of the buffeting here. For example, Horwich concludes, from his own lengthy and detailed analysis, that the liquidity-preference theory (1) is incompatible with the view that saving and investment cannot directly affect the rate of interest, and (2) involves a confusion between the allocation of additional saving to cash balances and the holding of additional cash.

Amidst such clashing views on topics in which the reviewer himself has more than a passing interest, it is difficult indeed to resist the temptation to take up the cudgels oneself. But when a review is all that has been requested, a review *article* should not be permitted to result. Thus the temptation will be resisted, and further comment limited. It should be said before closing, however, that Horwich ought to be highly commended for making a substantial contribution to the literature. His analysis is complex and quite difficult to assimilate; but it is also frequently illuminating and often extremely provocative. Not the least of its merits, moreover, is the fact that it provides us with just the solid basis for healthy controversy through which we may hope that the present condition of monetary theory will be most rapidly improved.

*Impacts of Monetary Policy.* A Series of Research Studies Prepared for the Commission on Money and Credit. Englewood Cliffs, N.J.: Prentice-Hall, Inc., 1964. Pp. 688. \$7.50.

Each of the contributors to this collection of CMC supporting papers (Suits, Eisner and Strotz, Kuh and Meyer, Grebler and Maisel, Phelps, and Friend) was charged with the task of summarizing and appraising the present state of knowledge of the factors determining spending in a major economic sector. Special attention was to be accorded to the question—is spending in a given sector responsive to general monetary policies? Most of the contributors to this volume would apparently answer, "Who knows?" or words to that effect. Considering the thoroughly Keynesian tenor in which the question was generally interpreted, this uncertain response would have to be rated as a concession to the claims of resurgent monetary theory.

Daniel Suits and Irwin Friend, in separate papers, scrutinize two sides of virtually the same coin—the determinants of consumption (Suits) and savings (Friend). There are, of course, important differences of emphasis. Suits examines the factors influencing consumer spending on durables, nondurables, and services, while Friend is concerned with the composition of savings and with business and governmental as well as consumer savings. But in

their discussion of aggregative consumer behavior, they cover similar ground, and share a common reluctance to admit that consumption may be a more stable function of wealth or permanent income than of current income, a common affinity for the distribution of income as an important, albeit unverified, influence on saving, and a common skepticism that monetary forces have much effect on consumer expenditure behavior. Friend looks for the effect primarily in the relation between interest rates and savings and finds practically none; Suits looks for it mainly in relations between liquid assets or consumer credit terms and consumer expenditures on durables and finds very little. One wonders if Suits, in the light of the Friedman-Meiselman study, would still say that "none of the studies of the effects of monetary factors on consumer behavior has succeeded in showing an unambiguous, statistically significant, important direct effect." Surveyors of knowledge are of course entitled to a few preoccupations with pet ideas. For Suits it is the interesting suggestion that family consumption is more autonomous and family income less autonomous than is generally supposed; for Friend it is the shopworn suggestion that an increase in desired savings may be self-defeating, for the usual "paradox of thrift" reasons.

Robert Eisner and Robert Strotz assay the determinants of business investment in a joint paper. The result is an important contribution to the literature on investment, thanks largely to the excellent chapter on the theory of investment of the firm by Strotz. Among other things, it is shown by a straightforward application of the calculus of variations that the distinction between fixed and variable factors of production is based on an economic consideration, namely that of maximizing a discounted net profit functional in which the cost of plant expansion depends on the time rate of expansion and the promptness with which the planned expansion is completed. Formulating the investment problem in this manner enables Strotz to provide a theoretical justification for the commonly used distributed-lag investment function in which the weights decline geometrically. Also, it becomes possible to provide a case demonstration that higher interest rates should tend to slow down the rate of plant expansion (i.e., investment). This dynamic or "interequilibrium" approach is distinguished from the Fisherian intertemporal theory of optimal investment. Regarding Fisher's approach, it is shown that multiple or non-existent "internal rates of return" have satisfactory economic interpretations although the internal rate of return is defective as a general investment criterion.

The bulk of the Eisner-Strotz paper consists of summaries and evaluations of the principal quantitative investigations of investment in plant and equipment and inventories. (George Post's useful bibliography of articles on investment, 1945-61, is appended to the paper.) One lesson to be learned from these investigations is to beware of the proxy variable—it may wander away from any close relation to the variable it purports to represent. Eisner and Strotz prefer modified capacity and acceleration models of business investment to those which stress profits and liquidity because the latter have no support in a profit-maximizing motivation of investment behavior and be-

cause profits may be merely a proxy for a missing accelerator mechanism. As to the effectiveness of monetary policy, the authors are of at least two minds. Eisner sees monetary policy as unable to affect the long-term rate of interest owing to the unresponsiveness of expectations of future short-term rates to the tentative reversible open-market operations that characterize anticyclical monetary policy. This is said to rule out any direct effect of monetary policy on long-term investment. Strotz is less adamant on this score, more willing to consider the possible indirect influence of monetary policy on investment via its influence on final demand, and more willing to admit that "changes in the terms of credit may be poorly represented by the tabulated changes in interest rates." He places considerable emphasis on the possible role of trade credit and other private sources of liquidity in affecting inventory investment.

Edwin Kuh and John Meyer search for new reasons why monetary policy need not have much influence on plant and equipment expenditures. One motive for the search is that they recently unearthed somewhat stronger evidence of an interest elasticity in investment demand among manufacturing industries than most previous studies, including their own, had shown. The most important new reason discovered is that even if business investment demand is interest elastic, variations in the level of interest rates might not affect the level of business fixed investment, owing to peculiarities of the investment funds supply schedule. If investment is financed more or less entirely from internally generated funds and the supply price of such funds is not responsive to market interest rates, then monetary policy is said to be ineffective. Meyer and Kuh's examination of the cyclical flow of funds in manufacturing suggests to them that, except near the cyclical peak in business, there is very little reliance on external financing of investment. Even this dependence has dwindled with the steady postwar increase in the portion of internal cash flow contributed by depreciation allowances. And in public utilities, heavy reliance on external financing does not mean monetary policy has an effect, because for various special reasons, the investment demand schedule of public utilities is said to be interest inelastic.

Despite their admission that "business liquidity and business financing can be influenced by monetary policy," Meyer and Kuh continually ignore the inference that monetary policy can affect investment via business liquidity. Repeatedly they equate monetary policy with manipulation of market interest rates and find this to be an ineffective stimulus to business investment. But the process whereby excessive business liquidity stimulates increased business expenditures—for inventories, plant and equipment, and the like—is a standard example of the equilibrating mechanism of the quantity theory of money. The quantity theory is, after all, most fundamentally a theory of the relation between money and expenditures, not between a small set of interest rates and expenditures or between money and a small set of interest rates. If they are properly interpreted, ten more such studies by Meyer and Kuh and the future of monetary economics in Cambridge, Massachusetts, might be assured.

Leo Grebler and Sherman Maisel offer a lengthy review of existing knowledge (or ignorance) of the determinants of residential construction. Between

incomplete models and faulty data the authors find much to discuss and little to praise. Verbal or qualitative models of construction activity have suffered from arithmetic triviality, untested or untestable propositions, and vague assumptions. Econometric models have not lived up to their promise, owing to the usual grab bag of statistical flaws (multicollinearity, serial correlation, errors in data, nonlinearity, least-squares bias) and ill-conceived specifications of underlying economic relationships. Worst of all, as Grebler and Maisel show in their useful series of tests on new data, the econometric models of construction generally forecast poorly by comparison with "naive" methods. However most of the models tested seem clumsy and unimpressive. A serious omission from the survey is Richard Muth's study of the demand for residential housing, which assimilates housing demand with capital theory, as it should be. One can agree with Grebler and Maisel's conclusion that more thorough models and better data are needed. It might also help if researchers in this field concentrated their attention on a few topics whose fundamental importance warrants the effort to improve both the theory and the data.

Charlotte Phelps examines the impact of higher interest rates on municipal capital expenditures in the 1955-57 period. She found that "from 4 to 7 per cent of municipal capital expenditures was postponed and/or cut back due to tightening credit." This seems like a trifling effect, but Mrs. Phelps apparently concludes that monetary policy has a significant influence on municipal investment.

*The Term Structure of Interest Rates.* By DAVID MEISELMAN. Englewood Cliffs, N.J.: Prentice-Hall, Inc., 1962. Pp. xii, 75. \$4.50.

The lack of independent evidence on expectations of future interest rates has been the chief obstacle to effective empirical testing of the expectations theory of the term structure of interest rates. Previous empirical work assumed that, if expectations did determine the term structure, one ought to be able to observe a correspondence between the forward short-term rates implied by the yield curve at a given moment of time and the short-term rates which later were actually observed. Such studies usually found that investors had been doing such a bad job of forecasting that it seemed doubtful that any forecasts had been made at all. In this Ford Foundation award-winning dissertation, David Meiselman argues that perfect-foresight approaches do not constitute valid tests of the expectations theory: "Anticipations may not be realized yet still determine the structure of rates in the manner asserted by the theory" (p. 12). Meiselman's contribution is the construction of an error-learning model which describes how expectations change over time with the receipt of new information. With this model, he is able to perform tests of the expectations theory which do not depend upon accurate forecasting for their validity.

Meiselman's conceptual framework is easily grasped with the aid of a simple example. Assume that as of the beginning of 1965 the one-year market

rate is 2 per cent, the two-year rate, 3 per cent, and the three-year rate, 4 per cent. Through the Hicks-Lutz averaging mechanism, this term structure may be considered to imply that the one-year rate expected for next year (1966) is 4 per cent, and the one-year rate expected for the following year (1967) is 6 per cent. Now let one year pass, and assume that the actual one-year rate turns out to be 3 per cent (100 basis points lower than had been forecast). An error-learning approach has investors respond to their error by lowering their forecasts of still-unrealized forward rates. For example, the expected rate for 1967, which had been forecast at 6 per cent during 1965, will now be reduced. Since, under the expectations theory, longer rates are averages of present and forward short rates, forecasting errors cause the whole structure of rates to fall.

Formally, the error-learning hypothesis may be written:<sup>1</sup>

$${}_{t+n}r_{1,t} - {}_{t+n}r_{1,t-1} = f(R_{1,t} - {}_{t+1}r_{1,t-1}).$$

Assuming the relationship to be linear, Meiselman estimated the equation

$$\Delta {}_{t+n}r_{1,t} = a + b(R_{1,t} - {}_{t+1}r_{1,t-1})$$

employing the annual Durand data. He found that changes in forward one-year rates were highly correlated with the forecasting errors and concluded that his tests provided impressive support for a modified expectations theory, one buttressed with an error-correction mechanism.

Difficulties are just now coming to light. Both Kessel and Wood have shown independently that it is possible to reinterpret the

$$(R_{1,t} - {}_{t+1}r_{1,t-1})$$

term as composed of a forecasting error and a liquidity premium. As a result, Meiselman's estimates do not discriminate between the pure and liquidity-premium versions of the expectations theory. Other critics have suggested that certain characteristics of the Durand data call the tests seriously into question. Applying the model to differently-constructed British data, Grant finds that Meiselman's hypothesis cannot be relied upon as an efficient explanation of the term structure. Grant's results seem to indicate that the construction of the Durand yield curves (particularly the methods of smoothing) may be partly responsible for Meiselman's surprising results. I have recently argued that behind Meiselman's work lies a certain view of the mechanics of the securities market which is in conflict with the actual workings of the market. Once one drops the untenable assumptions of costless arbitrage and identical expectations, relative supplies do affect the term structure even if market participants are not segmented. From a policy standpoint, the matter is an important one since a pure expectations theory suggests that any attempts deliberately to alter the rate structure would prove nugatory.

In sum, Meiselman claims too much for (his interpretation of) the expectations theory by suggesting that it can offer a complete explanation for the

<sup>1</sup> Capital  $R$ 's represent actual rates, lower case  $r$ 's are expected or implied rates. The prescript gives the time period when the rates become applicable. The first subscript stands for the maturity of the bond, and the second subscript tells when the rate is observed in the market.

term structure. Kessel's recent work, showing that short-term yields have on the average been significantly below long-term yields, indicates, at the very least, that factors other than expectations must be accorded an important role in a complete explanation. A realistic theory requires that we take a more eclectic view of the determination of the term structure.

To express skepticism concerning Meiselman's major conclusion in its most unqualified form is not to deny that his study has been immensely valuable. In an adroit opening chapter he has succeeded in clarifying several theoretical issues, particularly those concerning the Hicksian liquidity-premium analysis. In addition, he has devised and executed an ingeniously simple empirical test which has helped dispel a cloud of suspicion from the expectations theory. I hope that Meiselman's model will be applied to other interest-rate data and that it will be adapted to other financial instruments. An error-learning approach has much to offer in helping to explain price relationships in the equity market. No serious student of financial markets can afford to disregard this study.

*Full Employment or Stagnation?* By J. M. CULBERTSON. New York: McGraw-Hill Book Co., 1964. Pp. vii, 252. \$5.95.

In his preface, Professor Culbertson states that "The high unemployment level and weak economic growth of the United States in recent years are . . . the cost of misguided government economic policies. The errors of policy, in turn, are not accidental, but rest upon certain fallacious economic ideas." The "fallacious economic ideas" which the author angrily attacks are those of the "traditionalist," the related "banking school," and the "Keynesian."

The traditionalist approach is one which finds virtue in economic discipline and privation. Its proponents call for belt-tightening and for fiscal responsibility. A recession is considered to be a needed and desirable dose of salts for the economy. For the traditionalist, an increase in the quantity of money invariably produces a rise in the price level. The banking school, on the other hand, accepts monetary expansion as both desirable and necessary so long as it "meets the needs of trade." The members of this school consider the volume of credit, rather than the quantity of money, to be the relevant target variable for monetary policy. According to the author, "Keynesians" are fellow travelers. Their doctrine is just as objectionable as the other two. In tacit accord with the traditionalists, the "Keynesians" accept both monetary restraint during periods of economic slack and procyclical changes in the maturity of the federal debt because they believe these factors to be unimportant. They do not refute the "needs of credit" concept because they do not believe that it does any harm.

Culbertson discusses these three doctrines throughout his book, and he adequately demonstrates the fallacies in their arguments. His most effective weapon against the traditionalist and banking-school doctrines is the liberal use of quotations taken from statements made by public officials. The pri-

mary target of the attack is Chairman Martin of the Federal Reserve System who is fond of using such phrases as "leaning against the wind," "proper flow of funds," and "redundant money" to characterize monetary policy.

Culbertson's refutation of the "Keynesians" rests on the observation that the velocity of money cannot become infinite. The economy cannot expand indefinitely with a fixed stock of money. If this proposition is true, then the quantity of money must make a difference, the author argues.

Culbertson discusses the policies which he believes resulted from the three doctrines. Among these are (a) the absolute decline in the quantity of money (demand deposits plus coin and currency) which occurred in 1959; (b) the slow rate of growth in the money supply during the 1960-62 period; (c) the attempts to lengthen the average maturity of the outstanding debt in 1960 and again in early 1963; and (d) the lack of increase in federal expenditures from late 1958 to 1960. The author argues that these policies were sufficient to produce the 1960-61 recession and they have produced the economic slack which has existed since then.

Culbertson presents ample evidence that economic policies were indeed misguided. His presentation is well constructed, and it should reach the lay audience for which the book is partially intended. Unfortunately, the author slips badly in his theoretical analysis and, therefore, does the same audience a disservice. In attempting to teach his audience that the quantity of money is *the* important economic variable, and in straining to knock down his Keynesian straw man, Culbertson slips into the same sort of empty theorizing for which he criticizes Martin and others.

According to the author, the quantity of money enjoys its place of prominence by virtue of the "cash ratio" and the "web of financial constraint." The former is the ratio of the quantity of money to GNP; a "determinant and predictable" variable in the short run and, apparently, a "constant" in the long run. Culbertson's web is best described by the following revealing quotation: "What governs total demands is a web of financial constraint. Its component parts are a determinate money supply and those customs and practices that determine people's behavior toward their cash ratio. These customs and practices, in turn, depend upon motives of caution and responsibility set against the background of a complex of ideas and planning assumptions as to the general shape of future economic developments." This is the only description of the concept which he offers.

An injection of new money into the economy fights its way through the web in the following manner: "Since the injection is independently determined and does not, in itself, cause anybody in the economy to want to hold more money idle, the presumption is that, through channels straight or devious, the money finds its way into expenditures."

This sort of theorizing leads the author to the following conclusions: (a) monetary policy is sufficiently powerful to achieve economic stability and growth; (b) we need only to look at the behavior of the quantity of money to judge the performance of monetary policy; and (c) time deposits are not a medium of exchange and, therefore, are unimportant.

Culbertson's primary domestic policy suggestion is that a tax cut is (was) not needed to get the economy out of the doldrums. What we need is a substantial increase in the quantity of money. A cut in tax rates which is not accompanied by an increase in the money supply is self-defeating; the web of financial constraint sees to this. An increase in the quantity of money, with constant federal expenditures and fixed tax rates, is not self-defeating; the predictable "money multiplier" sees to this.

Culbertson adds little or nothing to informed policy-thinking; he provides a distorted and confused analysis of policy for the lay reader. If he were content to argue that there is an obvious fallacy in believing that a tax cut not accompanied by an increase in the quantity of money is as expansionary as one associated with monetary expansion, few would disagree. To argue that the quantity of money is the only significant policy variable is to be unnecessarily dogmatic. Even the confirmed quantity theorist would admit such variables as interest rates, income, and stocks of wealth into his theoretical system. If pressed, the theorist would probably agree that, while the relationship between monetary variables and the level of GNP is potentially predictable, no one has been able to demonstrate empirically the extent of the influence. Such knowledge will never be obtained by using anachronistic concepts like the cash ratio and the web of financial constraint.

### Public Finance; Fiscal Policy

*Public Finance in Under-Developed Countries.* By RAM N. TRIPATHY. Calcutta: World Press Private Ltd., 1964. Pp. x, 288. Rs. 15.00.

The financing of government activities in developing economies has been considered in numerous studies of particular countries by International Bank and other tax missions, by U.N. experts, by royal commissions, and by individuals. There have, however, been very few general analyses of the question, those of A. R. Prest<sup>1</sup> and R. J. Chelliah<sup>2</sup> being the best known. The Tripathy volume has the same general coverage as these, but with greater reference to the literature of economic development. The task of preparing a study of this type is a very difficult one, given the wide variety of conditions in the underdeveloped areas of the world and the lack of first-hand contact by any one person with a large portion of the spectrum. Any such volume almost of necessity suffers from the operation of the elephant theorem, and in this instance, as with Chelliah, the side of the elephant is India.

Ram Tripathy's basic philosophy is that governments must play a major role in bringing about rapid economic development, in light of the inadequacy of market forces in doing so, and that taxation and other methods of financing constitute important potential instruments for shaping economic development along desired lines. He analyzes in detail various alternatives for

<sup>1</sup> *Public Finance in Underdeveloped Countries*, London 1962.

<sup>2</sup> *Fiscal Policy in Underdeveloped Countries*, London 1960.

financing in terms of the usual principles of government financing, with particular stress on the importance of the goal of development. The study is largely analytical and normative, with limited reference to experience in the field.

The first portion of the book is devoted to a review of the theory of economic development of underdeveloped areas and of the general role of fiscal policy in economic development, with stress on the inadequacy for such areas of the Keynesian-based fiscal policy doctrines of the developed economies. The basic source of unemployment in the less developed areas is lack of capital, not inadequate demand, and fiscal policy must be shaped accordingly.

Nearly a third of the book is concerned with various tax measures, a discussion which is neither particularly novel nor illuminating. The merits and disadvantages of each type of tax are developed at length, and the reader not infrequently is left with the conclusion that there are no taxes which are suitable for the conditions. Tripathy has considerable preference for indirect taxes, particularly excises, but argues for the use of income taxation as well, largely on equity grounds. He unfortunately ignores African experience with the graduated personal tax. The importance of land taxation is stressed, a problem of greater importance in India than in many underdeveloped areas. While rejecting an expenditure tax on administrative grounds, he favors excess-profits taxation. In the field of income taxation, particularly corporate taxation, he endorses the principle of a high rate of taxation coupled with numerous incentive devices to aid investment and channel it along the lines regarded as most important for economic development.

The last three chapters deal, respectively, with government borrowing and debt management, inflation as an instrument to facilitate economic growth, and profits of public enterprise as a source of funds for development. The difficulties in the way of effective debt management are stressed. Tripathy is not sympathetic to deliberate use of inflation to aid growth, but regards profits of government enterprises as a highly desirable source of funds, largely because adverse incentive effects are avoided.

Running throughout the discussion are several assumptions of major importance for the conclusions: the existence of a high degree of inequality of income and wealth (which is not true in some underdeveloped areas, including most of Africa); the failure of the high income groups to contribute significantly to economic development; and the relatively limited dangers of adverse effects on incentives from high taxation.

Most of the analysis, hardly novel, conforms with the conclusions of what may be regarded as "orthodox" thinking in the field. There are a few exceptions. He stresses the need for reducing luxury consumption, without noting the potential dangers of such a program for incentives. The ultimate fate of savings used for purchasing land is not analyzed. His conclusion that the retail sales tax is the simplest form of sales tax to operate in underdeveloped economies would be challenged by many. His discussion of the effects of income taxation on risk-taking ignores recent contributions to the literature. His statement that developed countries have been unable to develop satisfactory

expenditure taxes ignores the fact that they have not seriously tried to do so. His discussion of how an increase in the supply of money affects consumption rather than investment (p. 204) is not clear, while that of the role of the interest rate in developing economies largely neglects its rationing function.

The volume, on the whole, makes little contribution to the subject, and such contribution as it might have made is greatly reduced by two considerations. First, the analysis is extremely loose and careless, with constant failure to clarify assumptions, and a tendency to treat assumptions as having demonstrated relevance—which frequently they do not have. The other problem is the form of presentation and method of writing. The reader cannot escape the feeling that he is wallowing along through a sea of words, constantly pulled back by the undertow of repetition, impeded by lack of systematic organization, and plagued by awkward and ungrammatical sentences. There are endless quotations and references to what other writers have said and rehash of old controversies not relevant to his primary subject matter (e.g., excess burden, marginal cost pricing). Frequently the reader can distinguish quotations from original writing only by the better grammar of the former. If the book were half the length, with the repetition eliminated and the quotations reduced, the usefulness would be greatly increased.

*Tax Incentives for Industry in Less Developed Countries.* By JACK HELLER AND KENNETH M. KAUFFMAN. Cambridge: The Law School of Harvard University, 1963. Pp. xii, 288. Paper, \$4.50.

Developing nations now realize that the encouragement of private investment is a practical problem of the first importance. For the most part, however, the problem is still discussed in such superficial terms as "favorable climate" and the channeling of investment resources to "necessary" or "fundamental" activities. The need certainly remains for a more thoroughgoing comparative analysis of the variety of investment encouragement measures that might be utilized and for an assessment of the efficacy of incentive devices that have actually been used. This study attempts to fulfill part of this need with respect to tax-incentive laws, and it does so in a competent fashion that should be of particular benefit to those planning or administering a tax-incentive program. It is a worth-while addition to the series of publications emanating from the Harvard Law School's International Program in Taxation.

The discussion is most relevant for those countries in which tax incentives represent the major legislative effort yet undertaken to promote private investment—by way of partial or complete exemptions from taxes and special allowances under individual and corporation income taxes for accelerated depreciation or reinvestment. While this type of legislation is intended to induce domestic or foreign investors to initiate activities which they would not otherwise undertake or to increase their investments in already existing enterprises, it imposes at the same time an opportunity cost in foregone govern-

ment revenues, new differentials in tax-burden distribution, and additional burdens upon the tax administration. The central issue is whether these revenue, equity, and administrative costs outweigh the advantages that the use of tax incentives may afford.

The authors begin with a chapter that surveys the discretionary or selective statutory patterns and the more automatically operating nondiscretionary patterns of tax incentive laws. Not surprisingly, this chapter concludes that where an incentive statute calls for selective discrimination in the designation of individual benefit grantees and in the tailoring of benefits to their individual circumstances, a higher degree of administrative proficiency is required than is ordinarily available in less-developed countries. If tax incentives are used at all, it is therefore more appropriate to rely on a more automatically operating statutory pattern of providing for accelerated depreciation or special reinvestment allowances in the income tax law.

The next chapter confronts explicitly the problem of balancing the potential gains of incentives against their costs. It is rightly noted that for many countries the tax system is relatively unimportant, compared with other factors impeding investment, and that tax relief seems to be of only secondary importance in creating conditions conducive to industrial growth, especially when the objective is one of increasing the level of new investment instead of merely promoting reinvestment. Given the low utility of tax incentives, the analysis suggests that for most countries the costs outweigh the advantages.

Remaining chapters concentrate on the role of income tax exemption, procedures for evaluating the effect of incentives on profitability, and accelerated depreciation policies. Regarding income tax exemptions, the authors conclude that, in practice, the benefits are generally less than would be indicated by theoretical considerations alone because of the desire of governments to attain a certain kind of development and because of the nature of the administration of the laws. On the basis of an empirical survey of the results of exemption laws in Mexico, the Philippines, and Puerto Rico, it is also submitted that income tax exemption is unlikely to be a desirable method of stimulating investment: it is difficult to administer, makes the tax system inequitable, and increases the probability that the government will be unable to finance needed expenditures without inflation. To evaluate the effects of incentives on the prospective rate of return, a compound-interest method for quantifying the effects is applied to the various cases of no incentives, exemption from import duties, exemption from income tax for a limited time, and straight-line depreciation for the same time period. Working through these cases entails some tedious "turning of the crank," but it is recognized that this type of quantitative evaluation is not a substitute for judgment and general qualitative evaluation. The discussion of accelerated depreciation and investment allowances is also based on a set of theoretical calculations, primarily designed to analyze the influence on the rate of return, risk and financial resources. Special attention is given to the cost of such incentives in lost revenues. Investment allowances that offer a deduction for income tax purposes of a proportion of the cost of an asset in the year of acquisition with-

out altering the basis for ordinary depreciation are judged the better alternative to accelerated-depreciation procedures for countries wishing to purchase the greater incentive per unit of revenue loss during the first 10 or 20 years of an incentive program.

The tenor of the entire study is workmanlike, and the authors present no exaggerated claims for their theoretical insights or quantitative illustrations. They recognize that the tax factor is but one factor in the investment decision, and they give no support to any notion that investment-incentive laws can be designed as though the types, quality, and amount of investments could be directly influenced by precise, statutorily prescribed and oftentimes small variations in the amount of tax reduction granted (p. 57).

Much of the discussion, however, is based on an administrative and legal approach, and development economists will feel that more could have been made out of the economics of the subject without sacrificing—but instead strengthening—the essential noneconomic aspects. The problem of promoting private investment cannot now really be separated from the problems of development planning. Yet this relationship is not pursued with much insight; accordingly, the economic analysis remains oversimplified and only tangential to some central issues. No substantial differentiation, for instance, is made between domestic and foreign investment. Inadequate attention is given to the use of tax incentives to channel investment to fit the objectives of a development plan. Nor is there little more than a hint of the important interrelations between development planning, import-substitution, and industrial investment. Indeed the entire argument appears exceedingly narrow in comparison with a study that would have sufficient sweep to place the particular problem of tax incentives into the more general context of a wide array of alternative devices for promoting and allocating investment in a development program.

### International Economics

*A Study of Economic Growth and International Trade.* By BO SÖDERSTEN. Stockholm Economic Studies, New Series, V. Stockholm: Almqvist & Wiksell, 1964. Pp. 190. SKr. 38; paper, SKr. 28.

For better or for worse, what is usually referred to as the Heckscher-Ohlin approach now dominates the theory of international trade and investment. The modern graduate student is familiar with the standard two-by-two-by-two model (two countries, two factors, two products) and thoroughly drilled in the comparative statical manipulation of it. If he cannot tell you offhand just what will be the effect on wages at home of an increase in population abroad, at least he knows how to find the answer—the Heckscher-Ohlin answer.

But of course it takes time to calculate: it would be easier to consult a card index. Bo Södersten has provided us with such an index. For a clearly defined class of comparative statical exercises he has provided us with a well-

nigh complete compendium of answers. Given the disturbing parameter, say, population abroad, and the variable of interest, say, the home wage rate, one has only to turn a few pages to discover the required total derivative.

The parameters in which Södersten is interested all have something to do with growth; they include the labor force at home and abroad, the stock of capital at home and abroad, and an index of technological efficiency, one for each industry, at home and abroad. The variables, the responses of which form the subject of Södersten's calculations, include the terms of trade, the level of output of each commodity in each of the two countries, the real national product, real income, and the distribution of income.

As a bonus Södersten has provided a brief penultimate chapter in which he abandons neoclassical production functions and reworks some of his problems under the assumption that coefficients of production are fixed, but demand is such as to assure the full employment of both factors. There is also a final retrospective chapter in which Södersten sketches the history of some of his problems and which is notable for a crushing dissection of Dr. Raoul Prebisch's theories.

The job was worth doing and Södersten has done it well. His style is as graceful as the subject matter permits, and his notation is happily chosen. Only on two rather minor matters would I wish to quibble. Thus Södersten makes a good deal of the generality of his treatment, in particular of his refusal to follow tradition in assuming constant returns to scale. But he does assume a competitive equilibrium, with the price ratio equal to the slope of the production possibility curve. How this equality may be reconciled with variable returns to scale, however, is not made clear. It can be done, by resort to externalities, for example. But the externalities must be of a very special kind indeed, and one wonders if Södersten has realized how limited is his additional generality. My second quibble concerns an unguarded passage on page 83. Södersten is there discussing the impact on factor rewards of a change in the factor endowment, with production functions which are unspecified but which might be homogeneous. He appears to deny that, if the terms of trade are constant, if production is incompletely specialized, and if production functions are homogeneous, factor rewards will be insensitive to the change in endowment.

*The Dollar Crisis—The United States Balance of Payments and Dollar Stability.* By NASROLLAH S. FATEMI, THIBAUT DE SAINT PHALLE, AND GRACE M. KEEFE. New York: Fairleigh Dickinson University Press, 1963. Pp. xvii, 317. \$8.95.

This book, the first in a projected series from the Institute of Foreign Economic Studies of Fairleigh Dickinson University, is a disturbing example of a tract that fails to give plausible support to its assertions, while at the same time claiming the standing of a research study. The trouble is not the conclu-

sions, nor the strength of their expression, but the quality of their substantiation; in fact, the analysis is superficial.

Some of this ambivalence is evident from the Foreword, which speaks with the multiple voice of the Committee on Economic Research. "It is the thesis of this study that the present situation [of the U.S. balance of payments] has been brought about by a number of complex and interrelating factors . . . and that there is no single cause at the root of the problem" (p. ii). Yet (p. iii), "the problem, we believe, is being rendered chronic by the policies and spending programs of the United States Government in relation to economic and military aid as well as the maintenance of an excessively large military establishment abroad." The reader will not be expected to take very seriously the concluding statement that "it is not the purpose of this study to defend any particular thesis or to cast any blame for the unfortunate condition which exists" (p. iv). The didactic intent of the book is reinforced by the Introduction, of which a series of policy prescriptions accounts for two-thirds of the space.

The method employed by the authors is to take the categorization of the main tables of the U.S. balance of payments and to devote separate chapters to each of the principal components. The text is supplemented by no less than 103 tables, many of which are derived from the Department of Commerce statistics. Partly as a result of this, the problem is seen as almost exclusively a U.S. problem rather than a matter of international economic relations. Since the reference is mainly to the period 1950-62, the problem is the cumulative effect of the over-all deficits in U.S. transactions. Thus the policy prescriptions are for what we should do about it, or rather what the U.S. government should do about its own affairs, since "the . . . deficits since 1957 have not resulted from any serious imbalance within the private sector" (p. 293).

Not all of the deficiencies of the analysis are attributable to the complexity of the subject. There is only the slightest attempt, for example, to estimate what part of U.S. merchandise exports (nonmilitary) is associated with U.S. government grants or loans. With the exception of brief references to the Commodity Credit Corporation and the Export-Import Bank, these exports are regarded as credits to the private sector account. There is, moreover, a completely arbitrary exclusion from the category of service imports of U.S. military expenditures abroad. The subsuming of these expenditures under "unilateral transfers" is not even argued; the authors blandly discuss (p. 241-43) how much of them were absorbed by offshore procurement, troop outlays, contractual services, and so forth. It is difficult to avoid the inference that the intent was to magnify the aggregate of U.S. Government Transfers Abroad (military expenditures, economic aid grants and net government loans) in Table 12.

On the other hand, the complexity of the subject appears to be admissible only when the discussion centers on private transactions. "The effects of direct investment on this country's balance of payments do not lend themselves to facile or definitive measurement. . . . The variables and inter-relationships

involved in this process are numerous and complex" (p. 166). The apologetic attitude reappears in the discussion (p. 175-76) of possible conflict between profit-seeking and the best interest of the United States; the displacement of domestic output by imports from foreign subsidiaries is styled "the path of least resistance."

Since the subject is complex, there is reason to be critical of some of the statistical juxtaposition used by the authors. In Table 91, for example, there are compilations, for each of six countries, of merchandise trade with the United States, military expenditures by the United States, holdings of dollar assets by their nationals, and official gold holdings. There is no mention here that these countries have in the past few years been making sizable net repayments on U.S. government loans; the emphasis is all on "the accumulation of large dollar surpluses which have been used quite freely to build up gold reserves" (p. 247). Moreover, it is not apposite to quote the total of military grant aid received by certain countries in 1950-61 and follow this with the prescription, "In view of the serious and continuing deterioration in this country's balance-of-payments position and the rising budgetary deficits, it would seem that one of the most obvious economies the Administration could make would be to discontinue forthwith military assistance grants to the dollar-surplus countries of Western Europe and Japan" (p. 261).

Nowhere, however, does the nationalist and bilateralist attitude of the authors appear more plainly than in the fact that the reader is within 25 pages of the end of the text before there is a mention that the dollar is an international reserve currency. By that time, it is too late for a serious treatment of international reserve adequacy. The authors, in any event, are more concerned about gold movements.

The basic question raised by this book is not whether there is a problem in our international economic balance, nor how to deal with it. It is whether there is any excuse for an academic research institute's issuing a political pamphlet superimposed on compilations of official statistics.

*Domestic Interests and International Obligations—Safeguards in International Trade Organizations.* By IRVING B. KRAVIS, Philadelphia: University of Philadelphia Press, 1963. Pp. 448. \$8.50.

Professor Kravis opens this timely and useful book by observing that cooperation among countries to ensure the orderly marketing of traded products creates conflicts between obligations under international commitments and interest groups. The major remedy is to include safeguards against injury, balance-of-payments difficulties, failure to receive anticipated benefits, or inconsistencies with other government programs in the treaties and agreements setting up international trading organizations. Such safeguards usually provide for renegotiations of the agreements, derogations from their provisions, exceptions, and adjustment assistance.

Kravis analyzes the safeguarding provisions of the General Agreement on

Tariffs and Trade, the Organization for European Economic Cooperation, the European Coal and Steel Community, and the European Economic Community and reviews their use in each organization. The main part of his book describes the background, structure, administration, safeguard experience, and operation of each organization and evaluates its general effectiveness.

Kravis is interested only in the question of cooperation among member countries and in showing how these four organizations met specific problems through the use of safeguards, not in whether the organizations themselves best met the needs of closer international economic cooperation. There is almost no discussion of the effectiveness of the organizations in expanding or rationalizing trade or of their possible negative effects in diverting it. Kravis thus seems to take the meaning of the term "international obligations" too much for granted and so fails to make clear its necessary relationships to domestic interests.

The second part of the book is a compendium of safeguard cases; one should consult it if he wishes to know how waivers were used and by whom under the GATT, how the ECSC handled the Belgian coal crisis or the marketing of steel scrap, etc. As a compendium this section is both comprehensive and authoritative; Kravis has provided a valuable service in putting this large amount of material into readily accessible form. Its organization, however, tends to obscure the role which the trade agreements played in the formulation and implementation of national commercial policies. Did the OEEC cause France to liberalize her trade faster than otherwise? Did the GATT restrain protectionist pressures in the United States and accelerate its tariff reductions? Kravis touches on these points, but the lack of extended discussion of the trade policy of any country in the context of its total international obligations leaves the reader unable to form an opinion. Such questions nonetheless bear heavily on the issue of national interests and international commitments. It is possible to argue, for instance, that France in the 1950's used the organizations to which she belonged to increase protectionism and to postpone necessary and beneficial currency and financial reforms that she might have been forced to adopt if left on her own. If the permissiveness of the trade organizations fosters such situations, it must be put on the debit side in evaluating their effectiveness.

The final section of Kravis' book seeks to draw lessons for a bolder U.S. trade policy from the successful safeguard experience of Europe, particularly that of the ECSC and the EEC. Kravis ignores, however, the most serious problems in applying European experience to the United States. The integration of the Six is basically a far easier task than that of the numerous and diverse countries forming the GATT. Kravis notes that the EEC and the ECSC were predicated on the assumption that integration would cause little industrial dislocation. The similarity of labor and capital costs and the free mobility of labor among the member countries guaranteed this. The Community has made little progress in agricultural unification, on the other hand, because of the cost differences that exist in that sector. The immense differences between the relative labor and capital costs of the United States and the poorest industrial countries mean that nondiscriminatory and substantial tariff cuts

must inevitably cause the displacement of labor-intensive U.S. industries unless derogations are invoked. This is the fundamental dilemma of U.S. trade policy and it cannot be assumed away by asking, as Kravis does, for a firm commitment to a liberal trade policy at the outset. In this respect, moreover, Europe has made as little progress as the United States and has instead sought trade arrangements having the greatest political and the least economic meaning.

In treating reconciliation policies in a systematic way, Kravis is one of the few economists to recognize what is the most important issue in trade policy. His book does not show, however, that safeguards are the best form of reconciliation or that experience is necessarily the best guide. More theoretical attention must be devoted to the problem of what is to be reconciled and how best to do it. The problem is to devise liberalization formulae and bargaining procedures that will automatically offset domestic interests against one another and that will also minimize the displacement costs necessary to achieve a given degree of effective trade liberalization. This would indeed seem to be the lesson of Kravis' book which reveals that "In each of the trading arrangements considered . . . the conflict between domestic interests and international obligations has been resolved in virtually every important case in favor of the former."

*Massachusetts Institute of Technology*

*Britain and the Postwar European Payments System.* By GRAHAM L. REES. Cardiff: University of Wales Press, 1963. Pp. 291. 42s.

This book, the author tells us, began as a study of the European Payments Union (EPU). As such, it will fill an important gap in our bookshelf on postwar financial arrangements. It provides a thorough summary of EPU operations and a judicious appraisal of the Union's contribution to the liberalization of European trade and payments. As a study of British policy, however, it falls far short of the promise conveyed by its title. There is, indeed, much less discussion of British problems and British attitudes than we require for a complete understanding of the EPU itself and of the long trek to convertibility. When Graham Rees does discuss the British position, moreover, he does so without questioning its origins, premises, or implications. His silence seems to convey a sweeping endorsement of postwar British policy, even when that policy obstructed rapid progress toward the objects that Rees has endorsed. Rees dwells at length on the proposals for an early "dash to convertibility" and on the British Government's brief flirtation with flexible exchange rates, but he gives us little insight into these episodes—into the internal debates on the proposals or the expectations of the chief protagonists, into the implications of the British position for the evolution of the EPU, or into the reasons for the ultimate retreat from those proposals. Rees has little more to say concerning the attempt to recapture sterling's ancient role in world finance and the consequence of this commitment for British policy toward Europe. He does not even mention the prolonged debates in EPU concerning the scope of ex-

change-rate guarantees—a debate that much exacerbated the negotiations and has continued relevance for sterling and the dollar.

These omissions would not be too serious if Rees had referred the reader to the several other works that study British policy from the early postwar years until convertibility. Yet his book makes bare reference to Triffin's work and none at all to Bell or Polk or to this reviewer's own account. One wonders, indeed, whether Rees made any use of these other efforts or retraced this complex history all by himself.

But Rees's work on EPU has not been done before, and specialists will have frequent occasion to consult his account—especially the middle chapters. These contain a careful history of the EPU and of the slow advance toward convertibility. They also fix the technical detail of the period into a broader analytical framework. Rees strives always to remind us that credits and discrimination may distort the allocation of real resources and that the peculiar institutions developed in the postwar years represented a response to a larger payments problem. Rees has prefaced these key chapters with 40 pages of theory and closed his account with 40 more on recent financial developments and on the spate of new proposals for international monetary reform. These first and final sections are somewhat less interesting; they offer nothing new to the specialist, yet may rush past the neophyte. But they may help to set all the history in perspective.

Rees's book is free of major error, and his conclusions stand up to the facts. At times, however, he is elliptical or elides intriguing points. One wonders, for example, about the "various influential opinions held in the United States" that barred the early establishment of an effective clearing system (p. 72). One also wonders which variety of sterling could be bought for \$2.40 in 1950 (p. 106). The author errs, moreover, when he asserts that Britain would not normally permit transferable sterling to fall below \$2.78 after 1955 (p. 182); transferable sterling was well below that lower limit during 1955 and in most of 1956-57. Finally, Rees may also err when he describes the 1955 decision to support the transferable rate as though it was a conscious step toward convertibility (p. 160); others have argued that Britain backed into this important decision while seeking to curb commodity shunting.

Appraising the contribution of EPU to the liberalization of European trade and payments, Rees concludes that the Union made "a notable contribution to European recovery, for it provided a return to global multilateralism, improving greatly on the bilateral arrangements which it superseded" (p. 255). It is hard to quarrel with this appraisal, especially in retrospect. But Rees goes on to argue that EPU should have been terminated earlier, in 1954, because, he says, access to EPU credits gave European governments a continued incentive to discriminate against dollar goods. The striking liberalization of dollar imports after 1954 challenges this view (see Rees's own Table 32). One wonders, indeed, if the prolongation of EPU did not actually serve to mitigate dollar discrimination. A premature "hardening" of European settlements might well have put a brake on liberalization. Although EPU credit could not be used in lieu of reserves to pay for dollar imports, the need to use

reserves in lieu of that credit might have weakened Europe's will to remove discrimination.

Unfortunately, Rees's book lacks the felicity of style we have come to expect from our British *confères*. His sentences are very long, and the punctuation is confusing. His detailed account of EPU operations and of the transition to convertibility becomes very tedious because he insists on translating his tables into dreary prose. Rees's book would have gained from more patient editing, especially from care with the spelling of well-known names. But the steady diet of official publications on which he must have fed for many long months is hardly nourishing to crisp and lively prose.

*The Future of Private Pensions.* By MERTON C. BERNSTEIN. New York: The Free Press of Glencoe, 1964. Pp. xiii, 385. \$12.50.

This is an exhaustive, and at times exhausting, treatise on the role of private pensions in providing retirement income supplementary to the benefits from the federal Old-Age, Survivors, and Disability Insurance System. Most of the author's attention is devoted to the shortcomings of present voluntary arrangements. Unless these are remedied, he warns, the pressure will mount for greater reliance on compulsory, tax-supported governmental programs. Furthermore, improvements are urgent because the arrangements in effect today are determining the adequacy of retirement incomes 20 or 30 years hence.

Despite the progress of recent decades, Bernstein reminds us that levels of retirement income for the great majority of older people represent a sharp drop from living standards enjoyed during their working years. He sees the closing of a major portion of this gap between employment income and OASDI benefits for both the worker and his widow as the long-range objective for private pension programs. For this result to be achieved on a mass basis, he argues convincingly that pension equities must be preserved from present exposures to forfeiture and loss.

Employee turnover resulting from a combination of the mobility of labor and technological change prevents the accumulation of pension credits under the delayed vesting provisions contained in most private plans. Despite the marked trend toward earlier vesting and the growth of multi-employer plans in recent years, the author argues that too many employees never receive pension credits for the early portion of their working careers during which job changes are most frequent. These pension credits cost little to fund at young ages because of the long period of interest earnings. If they could be handled economically through a pension credit clearing house, a retired worker could receive a single pension earned under three or four or even more private plans.

This concept of a central clearing house is developed at length in Chapter 10. Bernstein recognizes the difficulty of translating credits under different private plans into monetary values for purposes of transferring equities

from one plan to another. He concedes that these transfer values cannot be precisely calculated on a mass basis, but argues that minor inequities are not important in relation to the goal of at least limited transferability. This machinery to preserve pension equities is advocated as the most practical method of assuring a higher level of ultimate benefits for large numbers of the working population, especially those in the lower-income groups. The alternative of liberalizing benefit formulas without earlier vesting, in contrast, would only further concentrate the distribution of benefits to long-service employees and executives in the upper-income groups.

The organizational structure of this clearing house presents a multitude of problems, especially if it is to take over the custody of funds for individuals who leave covered employment to work either for themselves or for employers who have no pension plan. Determination of participation in and control over the operations of this institution presents difficulties which would daunt a proponent less dedicated than the author. When all of the complexities have been examined, the reader may well conclude that the vesting of pension credits in each individual plan is a simpler, more economical procedure with the aid of modern electronic data processing equipment.

Applying his legal training and experience, the author finds gaping holes in the protection afforded employees whose companies go out of business, merge, close plants, or otherwise liquidate portions of their total activities. Bernstein is at his best in arguing the case for employees who are separated in large numbers as a consequence of these kinds of corporate upheavals. He is less original and persuasive in his advocacy of flexible retirement arrangements.

The broad range of coverage does not include extensive economic analysis. For example, Bernstein treats pension costs simply as a part of wages and salaries, instead of as a portion of total outlays for placing a trained individual in a position to produce efficiently. The forfeiting of pension credits by short-term employees can be viewed as an offset to the costs of turnover and training replacements. Some observers attribute the current large volume of overtime worked in a period of uncomfortably high unemployment to the already substantial cost of fringe benefits for full-time employees.

In a broader sense, Bernstein's analysis is faulty at points because he assumes that adequate retirement income is a prime objective of most individuals. This leads him to the doubtful conclusion that a contributory feature for private plans, with limited tax deductibility for employee contributions, would greatly stimulate retirement saving among middle-income groups. The operation of state and local government retirement systems, which, incidentally, are guilty of most of the faults that Bernstein finds in private plans, suggest no such stimulus from the contributory feature. The facts are simply that raising families, education, home ownership, leisure-time activities, and the desire for a comfortable level of living in the present compete very effectively with retirement-income goals.

Bernstein concludes that "the future of private pensions will be whatever we make it" (p. 299). Perhaps he has interpreted this "we" too narrowly as being limited to lawyers, actuaries, economists, and public officials when in

reality the "we" is our vast industrial society, with white and blue collars greatly outnumbering academic attire or regalia of public office.

Taken as a whole, however, Bernstein's extensive efforts have produced a valuable critique of the emerging private pension structure. Lack of available data prevented him from providing a convincing answer to the key question: what proportion of employees covered at one or more times under private pension plans will ultimately receive pension benefits? His proposals would increase this proportion, but the extent of the improvement is not clearly established. Yet as a reference work or as a compendium of controversial proposals for improvements, this book deserves the careful study of all concerned with the role of private pensions in the American economy during coming decades.

*Unternehmensführung, Organisation und Entscheidungen.* By ERICH GUTENBERG. Wiesbaden: Betriebswirtschaftlicher Verlag Dr. Th. Gabler, 1962. Pp. 176. DM 18.

In the preface to this book the author states his disbelief in the possibility of a scientific discipline of top-managerial decision-making and his conviction that the art of formulating correct managerial policies can ultimately neither be taught nor be learned. There exist, however, a large number of managerial problems which are amenable to rigorous treatment. From among these the author has selected four major groups which he discusses in four loosely connected chapters: (1) the structure of top management (*Führungsgruppe*); (2) the nature of top-managerial decisions (*Führungsentscheidungen*); (3) the formal relationships between top management and the middle and lower managerial echelons; and (4) the nature of decisions on the middle and lower echelons. The book is neither a systematic text nor an original contribution but is rather a survey of important parts of contemporary organization and decision theories as developed chiefly in the United States. For in spite of the old *Betriebswirtschaftslehre* tradition, concern with scientific management in the U.S. sense of the term is of relatively recent origin in Germany.

To the non-German reader the most interesting chapter is the first one, in which the author gives an excellent comparative analysis of the locus and of the formal structure of top management in the German and in the Anglo-American corporate enterprise. The discussion of the difference in the roles assigned to the *Vorstand* and to the board of directors is particularly enlightening. The author also makes an interesting distinction between the German concept of *Betriebsführung*—which I have translated by *top management*—and the broad concept of *management* as used in English (p. 20). According to him there exists no German term corresponding to *management*, which

seems to indicate a difference not only in linguistic habits but in facts and attitudes.

The proper areas for top-managerial decisions are said to be: formulation of long-run policy; coordination of the major constituent parts of the enterprise; correction of maladjustments; nonroutine measures of particular importance to the whole enterprise; and appointments to top-managerial positions (*Führungsstellen*). It is typical of top-management decisions that they must be taken under conditions of uncertainty while those delegated to the middle and lower levels of management are taken under conditions of calculable risk or of certainty. In ten pages (pp. 80-90) the author gives an interesting geometrical treatment of decision-making under uncertainty. These decisions are said to be based on original probability indexes assigned to the expected results of available alternative courses of action ranging from, say, 0 to 10. Top management apparently has "certain ideas about the probability" (p. 80) of the future occurrence of any of the conceivable combinations of consumer and competitor behavior and of general trends. There is, however, no explanation of the process by which top management arrives at these ordinal probabilities. The rest of this chapter is devoted to a rapid survey of some alternative approaches to decision-making under uncertainty by W. Krelle, H. Koch, L. Hurwicz, L. J. Savage, and H. Simon and J. March.

The peculiar drawbacks of surveys become most apparent in the two last chapters, which deal with rather technical matters: internal structure, delegation of power, information and communication patterns, informal groups, decision-making by middle management under conditions of calculable risk and certainty. To the reader already familiar with procedures such as mathematical programming, game theory, etc., these sections have not much to offer. The reader who turns to them for technical information is likely to find them frustrating. For example, on pages 109-14 the author presents a simple case of assigning workers to tasks. Although mathematical expressions and tableaux are used, there is no explanation of the procedure by which the solution is obtained nor why it is superior to the one obtained by inspection. (Cf. also pp. 160-62.)

In this reviewer's opinion the weakest part of the book is a brief section on the informal groups and cliques which form spontaneously within the hierarchical and functional structure of the enterprise (pp. 147-52). These groups may have considerable influence on the morale and performance of the enterprise. The argument of this section is particularly superficial. No reference is made to the extensive empirical work being done in the areas of group dynamics and small-group research.

The faults of the book are, however, those of the class to which it belongs. On its own terms it is certainly a very good book which has a great deal to offer to the reader who requires only general information on, rather than a specialist's knowledge of, some major areas of current organization theory.

### **Industrial Organization, Government and Business; Industry Studies**

*Theories of Business Behavior.* By JOSEPH W. MCGUIRE. Englewood Cliffs, N.J.: Prentice-Hall, Inc., 1964. Pp. xix, 268. \$7.95.

This book presents a wide variety of theories about business behavior with critical comments drawn from the literature and some of the author's own comments. After two introductory chapters, one concerned with the general methodological problems of constructing theories and the next concerned with the problem of the concept of the firm, the author starts presenting the various theories in the third chapter.

There are three chapters dealing with the "economic" approach to the firm. The first presents traditional economic theory, the second presents criticisms of that theory, and the third presents alternative theories put forward by economists. The emphasis is on the objectives which the firm seeks and on the decision-making processes.

These are followed by two chapters concerned with more mathematical approaches to decision-making: linear programming, various criteria which have been suggested for decision-making under uncertainty, and the theory of games.

The next three chapters deal with approaches developed in the social sciences but outside economics. They present material which is not usually found in economics texts, although it is becoming more familiar to students of business administration. The first of these deals with theories drawn from sociology, the second from psychology, and the third from cultural anthropology.

The final chapter discusses some of the problems and ideas common to most of the approaches previously presented, and ends on the optimistic note that we are developing "better and more complete theories of business behavior."

This is too much ground to cover in depth in one short book, and the author tries only to give a brief survey so that the student can become acquainted with the principal ideas and problems which are now being discussed in the literature. The book can therefore be appraised on the basis of the selection of topics covered, the clarity of presentation, and the quality of the analysis and appraisal of the theories presented.

The coverage of the book is very good, given the initial decision to deal briefly with a large number of theories and authors. The footnotes are extensive and would serve as an excellent bibliography for the student. This reviewer would have preferred to see less attention paid to the technical details of some of the mathematical analysis (Chapters 6 and 7) so that some of the theories could have been analyzed more fully, but complete agreement about the appropriate weight to associate with such a large number of topics can hardly be expected.

The presentation is no more pedestrian or obtuse than one expects in economics texts. There are, however, some unfortunate errors which could create serious difficulties for the student. The worst examples are on page 147 where

the author says incorrectly that the appropriate combination of  $B_1$  and  $B_2$  can be found by solving a specified equation, and footnote 39, page 70, which says that the marginal product of each productive factor must be zero if the production function requires that the factor inputs be combined efficiently to obtain the maximum output. Other examples can be found in the equation on the bottom of page 59 (and the associated footnote 42, page 71) where the subscripts are incorrect, on pages 122-23 where the previously suggested outcome of \$102 is ignored, and on page 130 where there is confusion as to whether  $Y$  is an outcome or is the surprise which would be associated with an outcome,  $X$ .

The quality of analysis and appraisal of the theories are occasionally weak. On the one hand, the author too frequently fails to give any evaluation, as on page 20 where a paragraph of criticisms of Lewin's framework includes no indication from the author of their importance or relevance, and on page 37 where the reader is told to judge the usefulness of the various concepts for himself.

On the other hand, the author is not always consistent in his appraisals. In particular, he summarizes Friedman's familiar position on methodology (in part, page 9) as follows: "the realism of the assumptions of a theory does not matter so long as the theory permits accurate predictions of behavior." He concludes his discussion (page 11) by saying "that Friedman's position is untenable . . ." and recommending ". . . that our theoretical foundations be as realistic (in the sense of truth vs. falsity), as relevant, and as informative as we can make them."

As early as page 17, in discussing the problem of the concept of the firm, the author starts moving away from his recommendation and towards Friedman's position: "Criteria for judging the merits of such concepts as the firm do not necessarily include their relation to reality." In the last chapter, he joins Friedman's camp unconditionally (page 246): "if the choice must be made [between models whose assumptions are realistic and therefore intractable and those which have few enough assumptions to be tractable but are therefore unrealistic], it had better be made on the pragmatic basis of predictability. . . ."

*The Weapons Acquisition Process: Economic Incentives.* By FREDERIC M. SCHERER. Boston: Division of Research, Graduate School of Business Administration, Harvard University, 1964. Pp. xxi, 447. \$7.50.

This volume explores an important topic—the way institutional arrangements affect incentives when government arranges for the development and production of outputs. In this case the outputs are weapons, and the institutional arrangements are mainly the relationships between the Department of Defense and aerospace contractors. But indirectly much of the discussion is relevant to government purchase of other goods and services and to govern-

ment planning in general. The study brings out the difficulties, in such situations, of harnessing individual interests to promote broader interests and examines some of the alternative techniques for trying to do this.

In my view, exploration of this subject is much needed. For a long time, economists have studied the way the institutional framework affects choices and resource allocation in the private sector. They should now give more attention, using the same assumption that individuals are utility-maximizers, to the way the institutional framework shapes choices in the public sector. This book by Frederic Scherer makes some new progress along these lines. The analysis is generally sound, the observations are perceptive, the ideas provocative. For these various reasons, the volume should be of considerable interest, not only to those who are concerned about defense but also to persons who are interested in government activities, the problems of planning, and indeed political economy in general.

The book is divided into three parts. Part I deals with "competitive incentives"—that is, those generated by the competition among firms to maintain or increase future (profitable) sales to the government. Firms are sometimes rivals in developing missiles or aircraft that are close substitutes, and they are always competing for shares of the defense budget. Part II pertains to "contractual incentives," meaning those set up by the possibilities of increasing profits on particular contracts. These are the special forces, for example, that are introduced by the provisions of cost-plus-fixed-fee, fixed-price, or so-called "incentive" contracts. Part III, called "Incentives and Government Policy," examines a number of alternative policies. The work, it might be noted, is based to a considerable extent on case studies of development programs prepared in the Harvard University Weapons Acquisition Research Project and is closely related to the earlier work by Peck and Scherer.<sup>1</sup>

Among the major points stressed in the volume are the following. Contractors feel very keenly "user costs" (i.e., the possible sacrifice of future utility) and also the other side of the coin—the gains offered by actions that increase the chances of future sales, growth, and profits. In conjunction with the uncertainties and the nature of the bargaining process, this is said to produce much emphasis on improved weapon performance and early delivery and little emphasis on cost reduction. As a consequence, Scherer suggests that incentive contracts are not likely to have much impact on contractor behavior. Moreover he believes that the multidimensional incentive contracts (premiums for achievement along particular dimensions) may have harmful effects, by reducing the flexibility of contractors, making engineering changes more difficult, and obscuring the true uncertainties about Defense Department preferences.

Many other interesting points are discussed, far too many to summarize here. Along the way, the author mentions the similarity of the difficulties to those faced by the USSR in dealing with Soviet producers. Further exploration of this might have been enlightening. It is interesting to note, for exam-

<sup>1</sup> Merton J. Peck and Frederic M. Scherer, *The Weapons Acquisition Process: An Economic Analysis*, Division of Research, Harvard Business School, Boston, 1962.

ple, that, while the bargaining process here apparently leads to emphasis on engineering performance and delivery dates, the Soviet system, at least in many nondefense sectors, often leads to the sacrifice of quality and timeliness.

Although Scherer is usually careful to call something an improvement only if it brings more gain than cost, he slips, it seems to me, in talking as though less emphasis on quality and timeliness and more on cost reduction would *clearly* be an improvement. All of us would agree, of course, that costs should be cut if it can be done without impairing quality, etc., but we rarely know in advance of development what the quality-time-cost tradeoffs can or ought to be.

On a number of judgments I think Scherer is wrong, but even if he is, it does not detract significantly from the usefulness of the book. In my opinion he is a little inconsistent in stressing (Ch. 4) that contractors are seldom judged on the basis of past performance, yet (in various chapters) that they feel powerful pressures to increase weapon performance and reduce development time in order to get additional contracts. My judgment differs from his also regarding the advisability of awarding future contracts on the basis of after-the-fact evaluations of contractor performance by a single Program Evaluation Board. The dominant feature of the whole situation is uncertainty, and I believe a better hedge against uncertainties is achieved if contractors can sell in a variety of ways to a variety of clients than if great authority is given to a single evaluation board. The alternative policy changes, described in Chapter 13, appear more promising to me. But one's choices here depend on judgments about considerations that we know little about at present. Perhaps this stimulating study will lead to more tests of hypotheses and further increases in our knowledge of these matters.

*The Managed Economy.* By MICHAEL D. REAGAN. New York: Oxford University Press, 1963. Pp. ix, 288. \$6.00.

Joining those commentators concerned with the growth of private, corporate power, Professor Reagan issues the call for a form of economic introspection similar to the TNEC investigation of the 'thirties. He is distressed that our economy no longer possesses the mechanism that automatically converts the gain of the firm into the welfare of the community. Indeed the economy has changed "from a system of competition to one of administered resources and private planning, and as a consequence, the market itself has lost the regulatory power it formerly had." Not only has the market mechanism died, but no equivalent control has yet been introduced in its place. The role of the stockholder, for example, has long since been reduced to passive ownership. The consumer can hardly count since he is unorganized. And antitrust action, while applicable to the single-firm monopoly, is losing its relevance under oligopoly. Though the decisions of a few corporations, be they price, wage, or investment decisions, affect substantial portions of the economy,

these decisions are neither controlled by nor accountable to the community at large. Hence, we live in a "managed economy" in which unmolested, discretionary power resides within the private sector.

The author's policy prescription for this state of affairs falls under three proposals. A first reform is to submit large corporations to greater degrees of public control. In this regard Reagan advocates the federal incorporation of the top 200 firms—a suggestion attributed to the late Senator O'Mahoney. The author also proposes that a per se rule be applied to firm size within a relevant market as well as limits placed upon conglomerate mergers. Moreover, officials representing the public interest should be appointed to the board of directors of large corporations—in the manner of the recently formed Communications Satellite Corporation.

A second reform applies to the noneconomic activities of the large firm. Specifically, the author asserts the need to "repeal the privileged tax position now enjoyed by corporations for lobbying and for cultural, educational and charitable contributions, and new legislation preventing managers from spending corporate funds, with or without tax deductions, on political activities."

Finally, Reagan argues that national planning be grafted to business planning within the economy. Price and wage decisions would be accountable to public review; government would participate in the large firms' investment decisions; and manpower and industrial location decisions would be "institutionalized." All in all, the author advocates national economic planning as a device for controlling the exercise of private economic power.

The policy recommendations of the author appear to rest upon his pessimism regarding the vitality of competition as an allocating device. But there may be life in the market mechanism yet. After all, she is not very old, and she continues to display youthful recuperative power. Moreover, many of Reagan's proposals endow some two hundred large corporations with the status of public utilities. That this route is less reassuring is evidenced by the experience in the field of the independent regulatory commission. Nevertheless, this study's recognition of corporate power and its search for resolving that power within the framework of a democratic society is both relevant and provocative.

*Marginal Cost Pricing in Practice.* Edited by J. R. NELSON. Englewood Cliffs, N.J.: Prentice-Hall, Inc., 1964. Pp. 266. \$7.50.

Suppose that somebody wants to advocate the use of economic principles and theory for the practical problems of pricing. Where do you think he would look for examples? In a competitive sector of a liberal economy or in a monopoly of a planned economy? Presumably in the first one. Well, Professor J. R. Nelson does the opposite; he deals with the problem of marginal cost pricing in practice by choosing the case of the electricity supply in France. Everybody knows that Electricité de France (EDF) is practically a monopoly, that EDF is nationalized, and that the French economy is more and

more planned (although it is a "planification indicative et non impérative"). However paradoxical this choice may appear, I think it is an excellent one for the following reasons.

EDF is well known in France for being very much concerned with the problem of "fair" and efficient pricing as a national service. Some of the very best French economists are or have been working in the economics department of EDF: Mr. P. Masse, now the head of the French Plan; Mr. M. Boiteux, well known for his works on depreciation and on marginal cost pricing; and Mr. G. Morlat, an expert in production decisions under uncertainty.

Nationalization made EDF one of the three largest French enterprises. This created a lot of problems for efficient transportation and operating policies and led to research for establishing the "right tariff" by marginal cost pricing.

EDF accounts for 1 per cent of the GNP, but for 5.5 per cent of national investment; therefore, great efforts went to defining criteria for investment decisions. Such problems are particularly difficult in this case because (a) huge amounts are involved; (b) uncertainty appears both in demand (the peak demand is hardly predictable) and in supply (half of the production comes from hydroelectrical plants and the water supply is a random variable); and (c) the rate of interest is extremely important since the life span is usually long and since the permanent inflation phenomena have to be taken into account.

This book reproduces a group of articles which summarize quite well the results which French economists found in tackling these problems.

1. *Introduction*. Chapter 1 (Boiteux) briefly describes production and tariff aspects of the economic conditions under which EDF operates.

2. *Price Policy*. Chapter 2 is very general. G. Dessus wrote this pioneering article on pricing problems in 1949 as a report for a research meeting in Brussels. Chapter 3 (Boiteux) gives in four theorems a very brief and lucid analysis of the foundations of marginal cost pricing. Chapter 4 (Boiteux) applies the previous theorems to determine short-term and long-term pricing in several important cases: plants working close to capacity, first under constant demand and then under periodic peak loads. Chapter 5 (Boiteux) deduces from the previous results the marginal cost in every point of an interconnected electricity network, then the cost of distribution at low voltages, and finally the adequate tariff structures. Chapter 6 (Boiteux) gives the final result—the French *tarif vert* (green tariff) for electricity. Chapter 7 (Masse) tries to evaluate the efficiency of the *tarif vert*.

3. *Operating Policy*. Chapter 8 (Morlat) provides a decision rule for operating reservoirs of hydroelectric plants under water-supply uncertainty.

4. *Investment Policy*. Chapter 9 (Masse) deals with the problem of minimum cost investments under equal probabilities of failure. The importance of time and risk factors is stressed. Chapter 10 (Boiteux) goes into more details and refines the concept of "hydro-thermal equivalence." Chapter 11 (Masse and Gibrat) shows how linear programming can be applied to determine the optimum investment schedule under constraints. Chapter 12 (Masse

and F. Bessière) extends the analysis to prospective views, and a sequence of investment plans is studied for long-term programming. Here again, linear programming (with its dual form) is used.

To conclude, this book will give to the reader a very lucid view of the French results on marginal cost pricing and of the present trends of this line of economic thought. One might regret that very few comments and no transition are given by Nelson. The book is therefore a simple group of articles, and some repetitions are difficult to avoid. The reader finds, for example, exactly the same words on pages 137-42 as on pages 18-23. This is, however, a very slight reproach and, at a time when U.S. economists are more and more interested in European economic issues, I believe the reader will find this book very rewarding to study.

*Euratom—Its Background, Issues and Economic Implications.* By JAROSLAV G. POLACH. Dobbs Ferry, N.Y.: Oceana Publications, Inc., 1964. Pp. xxi, 232. \$7.50.

The European Atomic Energy Community (Euratom) has received little attention in the economic literature of this country, chiefly because atomic energy in general has not as yet performed well—to use Dr. Polach's expression—"as an instrument of economic change and growth." Yet President Johnson recently remarked, probably referring to progress in reducing capital costs and extending fuel life, that "the long promised day of economical nuclear power is close at hand." The critical moment for the new industry to become an unsubsidized competitor ought to be just as close in Europe where conventional thermal plants are usually less efficient than in the United States.

Dr. Polach describes in this monograph (prefaced by Sam Schurr, the author's senior colleague at Resources for the Future) the short history of Euratom, analyzing the events preceding its birth in 1957, its original scope, its infatuation with nuclear power, subsequent disillusionment and courage to switch objectives and to persevere despite resistance or snubs from member and nonmember nations, failure to assert supranational authority, as well as some accomplishments in building the infrastructure for a European atomic industry.

The Spaak Report of 1956 stated that the new Community was to assist "in creating conditions favoring rapid growth of nuclear industry" and to facilitate the use of nuclear techniques in other industries by means of the following methods: investing in research and in projects "as could not be undertaken alone by individual industries or countries," promoting mobility of physical and human capital, setting safety standards, establishing a clearing house for knowledge and techniques, and by assuring equal access to nuclear fuels. But the Suez crisis made Europeans nervous about their precarious fuel imports, and Euratom felt motivated to focus its efforts on the immediate development of electricity-generating capacity. The *Target for Euratom*, a docu-

ment regarded highly both in Europe and the United States, reflected this preoccupation with the mere availability of quantities in its forecasts of energy demand, to the neglect of proper consideration given to future price relations between the various sources of energy. So in fact, as Polach points out, the cost of conventional fuel was overstated and that of atomic power production judged too optimistically. That the quick production of nuclear electricity was neither technically feasible at the time nor economically justifiable became clear when the expected cost per kilo-watt-hour had to be revised upward several times and when lower crude oil prices and a slight recession led to uncomfortably large coal inventories.

Appropriately, the Euratom Commission shifted the emphasis of its activities to long-term goals, especially research and the preparation of qualified personnel. Large-scale power production was still part of its research program, but maritime propulsion, isotope utilization and the study of nuclear fusion were also included. The Commission also decided not to go it alone but to join with its funds and manpower in a number of projects undertaken privately or publicly in member countries and even outside of the Community (Britain and Norway). Since 1961 it also shared (only inside the Community) in the operating expenses of electricity-generating pilot plants, where technological changes were so rapid that without such support "no significant progress could be expected in the near future." Even though the Commission has little direct control over the national atomic industrialization schemes, it has nevertheless evolved into more than a mere coordinating agency. It is also credited by Polach with having fomented a "bandwagon psychology" in favor of continued efforts to make nuclear energy competitive. Official response was somewhat weak, though, since member nations preferred to give priority to their own plans, thus intensifying the competition for scarce technical resources and qualified manpower. Member governments also violated their treaty obligations by entering directly into agreements on atomic matters with nonmember nations, or they by-passed the Commission by seeking specific advice from other international organizations of relevant competence. France, with its well-integrated nuclear industry has tried persistently to exert its influence with regard to the control of nuclear fuel, the scope of research programs, and more importantly, the development of reactors burning available natural, instead of imported, enriched uranium.

Besides, one may, in retrospect, raise the question whether the Community, in its haste to achieve independence from advanced Anglo-Saxon technology, did not sacrifice long-run gains to satisfy a somewhat insular phobia or snobishness, as the case may be. In view of the acute initial scarcity of trained and experienced personnel, more might have been achieved by placing less reliance on home-grown developments.

Dr. Polach told the epic of Euratom very well, and only a few minor points may be criticized. Some of the numerous abbreviations in the text and in footnotes cannot be found in the glossary at the front of the book; a more consistent use of total amounts rather than differences would improve the comparability of energy requirements, ditto for consistency in the measures

of fuels (hard coal equivalents, barrels, etc.); the exuberant grand finale conclusion exceeds the otherwise well-observed limited bounds of this study.

*Resource Demand and Structure of the Agricultural Industry.* By EARL O. HEADY AND LUTHER G. TWEETEN. Ames: Iowa State University Press, 1963. Pp. ix, 515. \$8.50.

*Resource Demand and Structure of the Agricultural Industry* is the latest of several volumes on production economics to be developed under the direction of Professor Heady. It is an attempt "to describe how 'failure' elements of low income and 'success' elements of high productivity and capital accretion have their origins in the resource structure of agriculture" (p. 11). It is the authors' major contention that "while the problems of agriculture are directly those of commodity supply and price, basically they are problems of resource demand and supply" (p. 2).

The first five chapters of the volume form a rather separate unit. Together they provide the more general descriptive and theoretical background for the extensive empirical work that follows. For example, Chapters 1 and 4 deal with the relationship between economic development and resource use in agriculture, Chapter 2 gives a summary of resources used in U.S. agriculture since 1870, and Chapter 3 lays out the calculus of optimal factor use. Throughout these chapters, emphasis is on the relationship between product supply and derived resource demand, on factor substitution, and on the forces (such as education) that have influenced the resources used in U.S. agriculture.

The heart of the book is found in Chapters 6 through 15. Different portions of this unit are devoted to a rigorous empirical examination of the factors that influence the use of major inputs in agriculture, i.e., fertilizer, labor, plant and equipment, real estate, and operating inputs. Single-equation regression analysis is the major technique employed; and emphasis is on the predictive rather than the normative aspects of factor use. A large number of models are given for different regions, time periods, and levels of factor aggregation, and an attempt is made to estimate the effect on resources of changing price ratios, of complementarities between inputs, and of technical change. The last three chapters form the final unit of the book. Contained in this section are a regional input-output model of the agribusiness sector, an estimate of the aggregate (product) supply function, and an evaluation of the resource structure likely for the United States in 1980.

There is much in *Resource Demand* that is to be recommended. Any reader of the volume cannot help but be impressed with the immense amount of work that went into it. Estimates of over 400 equations are presented, and the ingenuity displayed in these models is impressive. Some of the more provocative findings suggest that "over 400 of the actual 512 percent increase

in weighted fertilizer and lime consumption from 1926 to 1959 remains to be explained by variables other than short-run price level," (p. 178); that with zero unemployment "a 10 percent decline in farm income relative to the income of factory workers could decrease the number of family workers [only] up to 1 percent in the short run," (p. 252); and that the price elasticity of demand for annual expenditures on plant and equipment "is approximately 1.0 in the short run (1 or 2 years) and more than 2.0 in the long run (3 or 4 years)" (p. 352).

In addition to the impressive empirical work, Chapter 2 provides an excellent historical summary of the changes in agricultural resource use in the United States. The discussion of farm investment behavior draws together the distributed-lag models relevant to agriculture in a neat, systematic manner, and the theory of static fertilizer demand presented in Chapter 6 is a skillful blending of agronomic relationships and economic theory.

Yet in spite of these merits and the tremendous labor input that went into *Resource Demand*, there are several reasons why the printed output is less than 100 per cent satisfying. First of all, major portions of the book are very difficult to read. A number of chapters were taken from different theses and research papers, and there is inevitable repetition and change of style. The presentation of so many equations makes for continual problems of notation; this difficulty is compounded by the authors' use of symbols rather than variable names in the text. In addition, the lack of adequate summaries at the ends of the empirical chapters makes it very difficult to comprehend easily the general meaning of the many statistical estimates.

One can also quarrel about the scope of the book. Individuals (such as the reviewer) looking for information about the effects of different types of government policy on the demand for resources in agriculture will be disappointed. Policy effects and policy conclusions are discussed rarely. There is nothing, for example, that deals directly with the current controversy of the effect of land retirement on the demand for fertilizer and other inputs. Even the supposedly broader sections that are concerned with "economic development" are limited to an examination of the U.S. situation since 1870. An additional chapter or two on policy matters and on the relevance of the U.S. findings for other countries would have assured without question that the volume had resulted in "more than a mechanical attempt to estimate demand functions of agricultural resources" (p. 12).

Finally, there are a number of issues that stem from the chapter on the prospective resource structure in 1980. While it is somewhat depressing to struggle with the elaborate models of the early chapters, only to find the final projections made primarily on a "straight-line" basis, these estimates should serve as a good stimulus to debate. Whether, in fact, the farm labor force will decline 48 per cent between 1960 and 1980 at the same time that total inputs increase by 10 per cent and total output by 47 per cent is dependent on a great number of factors, especially public policy towards agriculture. It is on the latter point that many will find the last chapter inadequate.

While few economists will find it worth while to examine in detail all of the

models presented in *Resource Demand*, many will find the central chapters an excellent source of empirical information. In addition, instructors will find the more general chapters good supplemental reading for advanced courses on the economics of U.S. agriculture.

*Transforming Traditional Agriculture.* By THEODORE W. SCHULTZ. New Haven: Yale University Press, 1964. Pp. xiv, 212. \$6.00.

The author's name guarantees this work will receive a wide, but not necessarily careful or objective, reading. In this small book Theodore Schultz, long-time conceptual-innovator in economics, continues to arouse intellectual ferment by attacking *dear dogmas* and *ill-construed concepts*.

He precisely defines traditional agricultural economies in terms of:

. . . an equilibrium at which agriculture gradually arrives over a long period provided particular conditions prevail. . . . The critical conditions underlying this type of equilibrium . . . are . . . (1) the state of the arts remain constant, (2) the state of preference and motives for holding and acquiring sources of income remains constant, and (3) both of these states remain constant long enough for marginal preferences and motives for acquiring agricultural factors as sources of income to arrive at an equilibrium with the marginal productivity of these sources viewed as an investment in permanent income streams and with net savings approaching zero (pp. 29-30).

His initial concern is with the relative costs of obtaining a given income stream from the alternatives of investment (1) in traditional factors and (2) in modern factors and technology. He first establishes the thesis that traditional agricultures are rather well organized and operating near the equilibrium maximum within their traditional resource framework. The cost of adding to the income stream within this context is "high" and accounts for the lack of noticeable savings-investment activity. In developing the thesis he disparages the widely accepted notion that agricultural labor in many such countries has zero marginal productivity.

He then considers the cost of adding to income streams by investing in modern factors and technology. This alternative provides potentially high rewards, i.e., is a relatively "low" cost means by which traditional agricultural economies may gain additional income streams. But the alternative involves a *transformation* process which is the central question and major concern of the writer. The incentives of farm people and the form of investments are both considered critical components in the process by which a traditional agriculture is transformed to a modern one. His proposition is that "differences in land are least important, differences in the quality of material capital are of substantial importance, and differences in the capabilities of farm people are most important in explaining differences in the amount and rate of increase in agriculture productivity" that occurs during transformation.

Schultz does discuss key aspects of the demand for and supply of both

traditional and modern factors. However, he keeps the reader's attention focused on the results emerging from the interplay of these forces, i.e., the *relative rates of return* from investments. He finds the rate of return to traditional factors low, providing a weak economic incentive, and the rate to modern factors high, providing a strong economic incentive to savings and investment.

It is quite widely believed by economists that the magnitude of the return to investment that is necessary to induce savings is greater in a traditional than in a modern agriculture. A conceptual justification is that people in a traditional economy have a higher marginal utility or preference for current above future consumption as a consequence of their low incomes. Lower levels of knowledge and higher risk and uncertainty of future attainments among people in traditional economies may give added weight to the argument. The implication of this line of reasoning is that economic incentives would have to be stronger in a traditional than in a modern agriculture to induce a given saving pattern. Although Schultz touches on some of these facets of demand for factors, he may have neglected to inquire into the relative strength of economic incentives between traditional and modern agricultures to the extent some readers would like. He was most concerned with emphasizing the evidence that people in traditional agriculture *do* respond to economic incentive, they are *not* handcuffed by custom and tradition, and that *economic incentives do play a major motivating role* in transforming a traditional agriculture into a modern one.

Some parts of Schultz's thinking will not be surprising to those who have kept abreast of his recent works. He labors somewhat to emphasize the importance of his general perspective that focuses on the transformation process as the major problem in inducing growth in underdeveloped countries. This reviewer shares the belief that it needs to be emphasized. Other perspectives that concentrate attention on the large returns that can be attained from relatively small investments in modern technology such as fertilizer, better seeds, and insecticides, have policy implications that are operationally questionable, if not logically distorted. They fail to bring to the forefront the prerequisite proposition that people and their institutions require economic conditioning if new factors and technology are to be absorbed and used efficiently.

Schultz's book is a welcome addition to economic development literature. It deserves careful study. A cursory reading and immediate reaction will likely indicate less "innovation" than is actually contained in the 212-page package.

*American Farm Policy, A Case Study of Centralized Decision Making.* By DON PAARLBERG. New York: John Wiley and Sons, 1964. Pp. xiv, 375. \$6.95.

Professor Paarlberg sees agricultural price supports as portents for a great issue of our times: "the degree to which decision-making should be an *individual* responsibility as contrasted with an *authoritarian* task." Rightly ac-

knowledging his approach to be empirical and pragmatic, a case study from which no scientific generalizations are warranted, he establishes his authority and offers his arguments and general conclusions. The author has clearly had unusual opportunities to observe and study farm programs during the last 30 years. Starting as a Hoosier farmer, he became an agricultural economist at Purdue, a position from which he took leave to serve as an administrator of agricultural programs in Washington during Eisenhower's administration. Students of farm policy, regardless of the degree to which they agree with Paarlberg's formulation of the problems or his conclusions, will find this factual, earnest, footnoteless volume a welcome and useful addition to their libraries.

Because the facts we choose to stress about farm price policy are largely determined by prior attitudes regarding the central problem, the large number of attitudes already recorded make it increasingly difficult to add anything both novel and relevant to the discussion. He has had, nevertheless, a degree of success. The message is short, clear, and direct. Government programs during the depression were "justified by the urgency of the times, by the failure of the free system to function in an appropriate manner, and by the lack of agreement on superior alternatives. . . . Government regulation of farm prices and production during the postwar period was harmful, in that the incentive prices provided more stimulation to the agricultural plant than the weak controls could overcome. . . . For some crops like tobacco, sugar and wool, individual decision-making does not appear to yield acceptable results." For them, centralized decision-making should be continued. But corn, cotton, and rice should again be returned to individual decisions, and that preferred status should be continued for livestock, poultry, fruits, and vegetables.

In its viewpoint, the book has much in common with Benedict (*Can We Solve The Farm Problem*. Twentieth Century Fund, 1955). Its orientation is less theoretical than Schickele's (*Agricultural Policy—Farm Programs and National Welfare*, New York, 1954). In regard to the inevitability of continuing governmental farm programs, the author's view is almost the opposite of that held by Hathaway (*Government and Agriculture: Public Policy in a Democratic Society*, New York, 1963).

For those who accept the author's premise that avoiding or limiting centralized decision-making really is the central problem of our time, the facts and arguments are likely to elicit ready acceptance and high approval.

Should one think that the level of employment, the distribution of income, or the rate of economic growth are the most important problems, he could use Paarlberg's facts to arrive at some very different conclusions.

In Chapter 22, for example, he outlines the dramatic adjustments and accomplishments realized in the farm sector during the past quarter century. They include wiser resource use which improved both the nutritive quality and the palatability of the American diet. Farms, enlarged to make use of the new technology, released to industry a stream of manpower such that farm population was reduced by 50 per cent. Geographic shifts in the location of crop production contributed to greater efficiency. Moreover, after these changes, nearly three-fifths of all farms were wholly owned by their opera-

tors; 62 per cent were free of real estate debts; and farm foreclosures in 1962 totaled only 1.6 per thousand in contrast to 39 per thousand in 1932. Could this mean that the \$17.7 billion dollars of realized cost of farm programs intended to stabilize farm prices and income from 1930 to 1959 (a sum equal to about one-third of one year's current military budget) may have aided adjustment? The author thinks not. "Most of these adjustments," he asserts, "were accomplished by the farm people themselves, without government programs. Some were achieved with the help of government-supplied research, education and credit. A number were achieved *despite* government programs."

Fortunately, we can learn a great deal about the politics of the commodity programs for "Corn, Which We Cannot Control" (Ch. 23), "Wheat, Which We Will Not Control" (Ch. 24), "Tobacco, Which We Have Controlled" (Ch. 25) and have the benefit of his good advice on "A Long Range Program For Agriculture" (Ch. 34), whether or not we find his economic metaphysics compelling.

### Labor Economics

*Unionism and Relative Wages in the United States: An Empirical Enquiry.*

By H. G. LEWIS. Chicago: The University of Chicago Press, 1963. Pp. xvii, 308. \$7.50.

It has now become almost commonplace to deplore the unformed state of wage theory in the body of economic doctrine. Although some of the imprecision of labor market analysis is attributed to the economic "irrationality" of the individual market components, the principal *bête noire* is generally found to be unionism—a powerful and often dominating intermediary in the interaction of supply and demand.

As Marshall's lengthy discussions of the subject indicate, the controversy over the union's impact on wages is an old one, coincident with the growing strength of organized labor. In the United States, the controversy was aroused anew in World War II and the postwar years as a result of the major collective-bargaining agreements—with and without strikes—in such industries as coal, steel, and autos. Congressmen and practical men of affairs were convinced that these wage settlements contributed significantly to the inflationary pressures of the period. Economists—as is their wont—stepped in to show that, even in such industries as coal and steel, unionism had little power to raise wages beyond nonunion levels. Others sought to prove that the non-economic facets of trade union policy resulted in rounds of collective-bargaining wage settlements which were substantially above the competitive norm. There followed an outpouring of studies, utilizing a variety of techniques, time periods, and levels of analysis, with conclusions as varied as the methodology adopted. To the casual observer, the postwar studies on the impact of unionism are frequently conflicting, and the composite findings are incon-

clusive. To paraphrase Kenneth Boulding's rhythmic conclusion, "When workers unite/To take dough from the rich/Wages go up or they don't/I do not know which."

Fortunately, Professor Lewis is no casual observer in this field, and he discerns order in the chaos. He makes a notable contribution in his careful review of empirical studies of unionism and relative wages, and he finds that much of the seeming disagreement results from conceptual differences in the particular wage effects examined, differences in time periods studied, and differences in the authors' choice of language for stating their conclusions. Utilizing a synthesis of these studies and his own investigations, Lewis' main purpose is to estimate the magnitude of the impact of unionism on relative (percentage) wage differentials among groups of labor. He attempts to give quantitative answers to such questions as: (1) How much has unionism increased the average wage of union labor relative to the average wage of all labor, both union and nonunion? (2) How have the average wages of different industries been affected by unionism? (3) How variable were the effects of unionism on relative wages from one date to another during the last 40 years? (4) How much of the relative inequality in average wages among industries and in the distribution of wages among all workers can be attributed to the wage effects of unionism?

Lewis' most significant findings concern the differential impact of unionism on wages in different time periods. Significance is gained here because there is considerable uniformity on this point in the studies under review. Students of the labor movement have long had an intuitive feeling that unions are more effective in maintaining wages relative to the nonunion sector in depression than they are in surpassing nonunion wages in a period of full employment and inflation. Individual authors have provided quantitative evidence of this differential time-period impact in particular studies. Lewis' contribution lies in his generalization of these estimates over a 40-year period. At the depth of the Great Depression (1932-33), the effect of unionism on the average wage of union workers relative to the average wage of nonunion workers may have been above 25 per cent. By the end of the 1930's, the relative wage effect had declined to a level between 10 per cent and 20 per cent; and the decline continued until the average union/nonunion relative wage effect of unionism fell close to zero—under 5 per cent—at the peak of the postwar inflation in 1947-48. However, the declining effect was reversed in the 1950's, and it is estimated that in recent years the average union/nonunion wage was approximately 10 per cent to 15 per cent higher than it would have been in the absence of unionism.

These estimates, based on other empirical studies, are buttressed by Lewis' own quantitative study of the effects of changes in the general price level on the average union/nonunion relative wage. High rates of inflation during the period, 1920-58, strongly tended to reduce—and abnormally low rates of inflation to increase—the effect of unionism on the average union/nonunion relative wage.

The author's efforts to reach estimates of the wage impact of unionism among industries and among individual workers are less successful because

of inadequacies in the required empirical data. He estimates that the majority of workers are employed in industries whose average relative wages have been raised or lowered by unionism by no more than 4 per cent. In industries employing a small fraction of the labor force (less than 6 per cent), the relative wage effect is 20 per cent or more. It is estimated that in 1958 unionism increased the relative inequality of average wage rates among industries by about 6 to 10 per cent. At the same time unions *reduce* the average wage inequality *within* industries (but by no more than 5 per cent in the economy as a whole). Thus the effects of unions in changing relative wage inequality among all individual workers in the labor force are small, probably less than 6 per cent.

In arriving at his estimates of the wage impact of unionism, Lewis has been faced with serious methodological and data problems—problems which beset the studies he reviews, which inevitably weaken his own conclusions, and which will continue to plague research investigators in this field for some time. Only two of these issues can be mentioned here. First, is the “threat effect” of unionism on nonunion wages. In order to forestall a union organizing drive, nonunion employers may raise wages to parallel union-negotiated wages in the same industry or community. Such a result might constitute a considerable impact of unionism on wages, and yet this effect would be obscured in statistical comparisons between average wages in union and nonunion sectors, plants, and industries. Although Lewis is not unmindful of this problem, he tends to minimize its significance. And yet the indirect “threat effect” may have been of greatest importance in the late 1930’s and the 1940’s when the union organizing drive was strongest and the political climate was most conducive to unionism. This is the very period in which the measurable direct effects of unions on relative wages were found to be smallest.

A second difficulty stems from the unreliability of data on the extent and strength of union organization, especially in particular industries. Although Lewis makes adjustments in “official” data on collective-bargaining coverage, it must be recognized that alternative reasonable assumptions might be made, and these might result in substantially different estimates, thereby affecting crucially the correlations between the extent of unionism and average wages.

Even though some might argue with Lewis’ assumptions and adjustments in meeting particular methodological and data problems, it should be noted that he is explicit in the choice of the alternatives before him and careful in expounding the reasons for his selection. One can ask for little more in this difficult and controversial area of research. It is safe to predict that all future studies of the wage effects of unions will be indebted to Lewis for his work in this useful and important volume.

*Workers Councils—A Study of Workplace Organizations of Both Sides of the Iron Curtain.* By A. STURMTHAL. Cambridge: Harvard University Press, 1964. Pp. x, 217. \$5.00.

The study examines the evolution of the works council, its operation in

two democratic and two totalitarian countries, and the relation of this institution to the labor movement, collective bargaining, and management. Several chapters evaluating these institutions and forecasting their future close this short and excellent study.

The works council is a special kind of worker organization, and it appears, at least to me, to differ from the shop groups established by an outside trade union to administer its contract and to aid its members. The trade union in the shop exists to protect the position of the worker it represents, and to promote his rights under the contract. It is true that, as Professor Sturmthal has noted, unions encroach upon managerial authority. They always have, and employers in the distant past were as concerned with the intrusion of the union in the domain of management as they are today. Yet there appears to be a difference between encroachment which is incidental to achieving certain protective purposes and the overt aim of intruding upon the collective powers of management.

The works council in France is traced to the pre-World War I syndicalists, from where it was carried and modified by the Italian fascists who adopted it as the corporate state. While the French syndicalists were, for their day, extreme revolutionists and antimilitarists, a number, including one of its leading editors, ended as supporters of Petain during the occupation. The idea had sufficient vitality to survive the liberation as the "plant committee." Its revolutionary origin does not mean that the works council is a vehicle for militant action. Sturmthal notes that "the main field of action of the plant committees . . . is the administration of the welfare activities of the enterprise."

Works councils in Germany have been, according to the author, more or less active since 1848. They had their day after the ousting of the imperial regime and were for a time centers for the more radical kind of activity. The detailed chapter reveals the reasons why councils are no substitute for a plant union. Aside from welfare activities, these councils do not appear to do very much. Moreover, their method of election makes them dependent upon the firm and frees them from the restraints which an outside union would impose upon activities. If an organization is to serve the interests of its members and not be a sort of dispenser of largesse, it has to speak with one voice.

The chapters devoted to Yugoslavia and Poland are interesting and informative. The works councils in those countries are not independent decision-making institutions. Governments recognize that force and pressure do not always yield the best results, especially over the long run. Like the legally inhibited American company unions, many of which were works councils, those east of the iron curtain can ameliorate minor inequities and mitigate the harshness and arbitrariness of subordinates, but they cannot oppose centrally determined policies. One need not deny that the councils may at times be a useful and even significant instrument for promoting labor welfare. But as Sturmthal notes, the decline in the position of the Polish councils began when they "were rapidly developing into a political threat to the party and the regime."

The four concluding chapters contain a number of cogent observations sup-

ported by reference to the discussions in the preceding chapters. One cannot avoid the conclusion that these councils are essentially agents of political groups or instruments of the employer. In Germany, as the author shows, the political parties seek to influence the councils because the postwar trade union movement is not closely linked to a particular party. All and all, the excellent study reveals that the councils have weakened the trade unions, that they perform minor functions, and why they are welcomed by the politicians of the left and those employers who would weaken organized labor.

*Unemployment and the American Economy.* Edited by ARTHUR M. ROSS. New York: John Wiley & Sons, Inc., 1964. Pp. xiv, 21. \$4.95.

*Unemployment and the American Economy* is the result of the first annual conference of a four-year research program on unemployment at the Institute of Industrial Relations, University of California (Berkeley), sponsored by the Ford Foundation. The conference was held during April, 1963, and it "included about seventy-five scholars, government officials, and representatives of management, labor, and community organizations from various parts of the country." As might be expected in a volume representing the views of such a diverse group of people, the quality and interest of the papers and comments to professional economists vary greatly. Also predictably, the papers are of generally higher quality than the comments, with two notable exceptions.

The papers and comments are divided into three major sections. The first deals with retraining and labor market policies; the papers are by William Haber and Seymour L. Wolfbein, with comments by E. Wight Bakke, Nathaniel Goldfinger, and Gerald G. Somers. The second is concerned with the problem of expanding economic activity; the papers are by Walter W. Heller and Otto Eckstein, with comments by Albert Rees, Paul W. McCracken, and Don Vial. The final section deals with the question of what the United States can learn from European experience. The papers are by Jack Downie (deceased) and Robert J. Myers; the discussants are Robben W. Fleming, William H. Miernyk, and Richard A. Lester. Arthur M. Ross has written both an introduction and a conclusion to the volume.

The first section is moderately interesting and presents a useful summary and critique of U.S. labor market policy regarding retraining, unemployment compensation, information services, and the like. Gerald Somers' comments in this section are cogently put forward and are especially worth-while reading.

In the second section, the interesting papers by Heller and Eckstein are probably the best of the volume. They argue forcefully that the United States does indeed have an unemployment problem which is not merely the result of improper statistical procedures in measuring the unemployment rate, that the unemployment problem is most likely due to an inadequate rate of growth of demand for output, and that the late President Kennedy's tax reduction scheme is the most satisfactory method of combatting this situation.

The first two sections leave the reader with the impression that the present unemployment problem is more the product of aggregate than of structural phenomena, and the evidence presented in the Heller and Eckstein papers is persuasive, if not complete. For instance, Heller points out that:

The main conclusion to be drawn from the analysis is that changes in the overall unemployment rate explain most of the fluctuations in unemployment in the specific occupations and industries [most commonly thought to be the source of structural unemployment]. Moreover, in general, the relationship between unemployment in these occupations and industries and the overall rate has not changed. If unemployment in blue-collar occupations and goods-producing industries is correlated with the overall unemployment rate and time for the postwar period, the partial correlation coefficient for the time trend is not significant, except for construction. In some instances—nondurable goods manufacturing and skilled workers—the trend coefficient is negative (p. 100).

The feeling of the reviewer after reading Sections I and II is that policies designed to combat structural unemployment are best thought of as long-run policies which are desirable regardless of the stage of the business cycle. Desirable policies are those which assist individuals in overcoming imperfections in the spread of labor market information and in access to resources for the support of education and training. Such policies may be thought of formally as implementing wage subsidies to certain groups of individuals and occupations. During conditions of tight labor market conditions with rising prices that usually accompany them, relative wages are rather free to adjust to the conditions of demand and supply in such a way as to alleviate extreme unemployment differentials by age, occupation, industry, and race. Under conditions of slack demand, however, as long as wages tend to be sticky downwards, these adjustments are hindered. Therefore, in periods of relative prosperity, training and retraining programs and the like may help reduce what appears to be an almost inevitable concomitant upward trend in prices, and during periods of relative depression, such programs should help mitigate the rise in unemployment rates.

In his comments on Section II, Albert Rees accepts Heller and Eckstein's analyses of the nature of the unemployment problem in the United States, but he is critical of their assessments of the danger of inflation and the proper "tradeoff" between inflation and high employment. There is a thoughtful outline of the effects of inflation and the only explicit suggestion in the volume that an alteration in our international monetary arrangements might be a desirable and even a necessary component of an effective anti-unemployment program. He points out (pp. 138-39) that:

Professional economists owe it to the public, and in particular to the unemployed and their families, to bring the issue of gold policy into the arena of open discussion. . . . It is fortunate for American policy makers that our unemployed have been so patient, but can we count on this indefinitely?

The third section, on unemployment in Western Europe and the United

States, is perhaps the least interesting of the volume. This is perhaps because it appears that there is nothing spectacularly different in European experience which sheds new light on the U.S. unemployment problem. European unemployment does appear to be lower than that in North America, even after differences in definition are considered. This seems to be because output and the demand for labor in Europe have been growing more rapidly than in the United States and possibly also because the European nations have been willing to adopt somewhat more paternalistic labor market policies than has the United States.

In general, the papers and comments in this volume are of sufficient interest and quality to make them recommended reading for intermediate and advanced labor economics classes. There are some glaring examples of undefended venting of old prejudices and positions which are perhaps inevitable in the proceedings of a conference of this type. Some examples are:

... the kaleidoscopic changes in technology, occupational structure, industrial location [and] the more exacting standards of performance to which the economy is subject [indicate] that there will have to be more extensive economic planning in the future than we are accustomed to now (p. 209).

... we need a lesser redistribution of income via the taxing mechanism (p. 142).

... it is a [well?] known fact that the rich have been getting richer and the poor have been getting poorer (p. 148).

Nevertheless, there are sufficient sound analyses and recommendations in the volume to make it of interest to both students of economics and to those concerned with the formulation of public policy.

### **Population; Welfare Programs; Consumer Economics**

*The Economics of Human Resources.* By H. CORREA. Amsterdam: North Holland Publishing Co., 1963. Pp. 262. \$7.00.

The economics of human resources, with its emphasis on the study of qualitative differences in the labor force, has become a subject of great interest to economists only in the past few years. This reasonably short book by H. Correa covers a wide range of topics in a burgeoning field, summarizing the existing state of knowledge in some places and extending it in others. The unifying thread is the elemental economic concept which permits the book to be divided into one half dealing with supply and the other with demand. Nevertheless the field has not advanced sufficiently to permit simultaneous consideration of all facets within an economic framework, and the various parts of the book therefore tend to live independent existences.

The first half is a review of the factors which work through the supply curve to determine the size and skill composition of the labor force. Most of the discussion deals with education, but the author also examines a wide

range of other determinants, including health, nutrition, and mental aptitudes. He has read widely in other disciplines, especially in education and educational psychology, and it is from a remarkable variety of sources that he brings references to bear on the issue at hand. Nevertheless this part of the book is not wholly satisfactory. Several times the author's line of reasoning comes to an abrupt halt because these other disciplines have not dealt with the problem he poses, so he is left with nothing to build on and must state problems without answering them. In a few other instances conclusions are reached only with the help of dubious assumptions or a questionable interpretation of the results of educational or psychological research. However, many of these inadequacies may be attributed to the author's having plunged into territory largely uncharted by the economist, and such a bold approach yields returns as well. The specialist in this field will profit from this survey of the research done by other disciplines and from the specification of problems yet to be treated in the depth they deserve. These problems amount to a catalog of needed interdisciplinary research.

In the book's second half, the author returns to more conventional economics and considers the relation between education and aggregate output. He does this first by assessing the growth of educational capital as a partial explanation of the large share of growth in output per worker which cannot be explained by increases in the stock of physical capital. This is a problem originally tackled by Schultz, and Correa follows Schultz's approach, as he acknowledges, but with some variation in both data and method.

Probably the most interesting chapters of the book are those concerned with mathematical models, presented in illustrative form and applicable to problems of educational planning, i.e., Chapters 8, 14, and 15. The last two contain an extensive exposition on educational programming in which an educational system has been superimposed upon a Harrod-Domar growth model. Output bears a fixed ratio not only to physical capital but also to each particular skill level in the labor force, and the function of the educational system is not only to supply the various skill levels in the desired quantities, but also to maintain itself through producing teachers. The model developed is a system of difference equations, and when Correa examines its stability conditions, he finds it to be unstable and explosive. Nevertheless a study of its equilibrium growth path is extremely valuable in showing the trend in the size of educational effort demanded by a growing economy. The model gains further interest as the author considers the educational effort required when the economy is raised to a higher equilibrium growth rate through an increase in the savings rate. By the workings of the model, a transition period of some length, during which the educational system builds up its stock of teachers, must precede the increase in savings and in the growth rate. If the growth rate is pushed up to some extent during the transition period, then more skilled people are drawn into production, and the stock of teachers is built up less rapidly.

A model of this sort should be of particular interest to planners in developing countries, where in many cases massive changes in the size of a nation's

educational system are occurring. It brings out very well the almost insuperable difficulties in realizing quickly the desire for universal primary education. However, while the model can thus provide useful guidance to the planner, it by no means solves all his technical problems. The statistical problem of determining appropriate education-output ratios is a difficult one in most countries, but an essential problem of educational planning is to see how flexible these coefficients can be made, not of measuring them once and assuming them fixed. This is particularly so when education is measured by years of school completed; this is a questionable technique in the United States, but is even more dubious in a less developed country, where quality is often a serious problem, and where it could be said that the educational problem is as much one of changing attitudes as of supplying knowledge.

There are two further elaborations of the model which deserve mention. In the first, separate consideration is given to each economic sector, so that the model becomes a dynamic input-output system, in which the educational sector is added to those conventionally included. In the second, income distribution is introduced into a simpler version of the model, and the conclusion is reached that "the concentration of income is detrimental to development, an idea contrary to that usually accepted" (p. 245). This reviewer must part company with the author on this particular conclusion, however, at least as a statement about the real world. It arises out of a series of unreal assumptions in the model: that capitalists save to invest only in physical capital, while workers save to invest only in education; that there are fixed factor proportions; and that investment in physical capital is realized very quickly, while investment in education is invariably realized only after a long gestation period.

Correa has written a book in a language other than his native tongue, an accomplishment to which the great majority of American economists, including this reviewer, must doff their hats. Nevertheless I must say with honesty that the book's literary style is not smooth, and the exposition is often more difficult to follow than it need have been. Therefore this may not be the book for the general economist who would like to learn a little about recent developments in the economics of education and human resources. For the specialist, however, and particularly for the educational planner, this is an important book which I would like to recommend.

*The Economics of American Medicine.* By SEYMOUR HARRIS. New York: The Macmillan Co., 1964. Pp. xvi, 508. \$8.50.

Probably no other field of enterprise has been so studiously avoided by U.S. economists as the distribution of medical benefit. Only a few experienced medical economists exist; they quietly enrich the curricula of three universities or busily collate statistics at The Brookings Institution or The Department of Health, Education, and Welfare. Nowhere in the United States does a competent and authoritative body speak for the outraged patient, as

it does in advanced societies elsewhere. When an occasional protest is heard against the absurd irony of U.S. medical practice—that amidst abundant facilities and affluent physicians there continue to be needless death and disability and bankruptcy generated through morbidity—it is uttered in most delicate phrases.

Such an occasional commentary is Seymour Harris' latest adventure in broad-spectrum economic analysis, *The Economics of American Medicine*. Here is set out, in just under five hundred pages, a rather summary discourse on factors influencing purveyors of medical and pharmaceutical goods and services and health insurance carriers in the pricing and allocation of their specialties. Those readers who are up to plowing through interminable qualifications (Harris calls them "offsets") and irritating classroom jargon will find solid proof that ratios of performance to cost in this sector are at a level which would be considered unacceptable in other sectors of the economy. Whether or not they are properly so seems to be Harris' main concern.

We are told that the over-all shortage of doctors, already severe, is steadily worsening. On the basis of a 45-hour week, there are not enough general practitioners in the country to allow each person an annual two-hour examination; and not enough doctors of any kind to permit everyone longer visits. Before the end of this decade the number of physicians must increase by 50 per cent, and 20 new medical schools must be opened, merely to maintain the present doctor-patient ratio. In an era of treatment whose greatest challenges are preventative medicine and degenerative disease, the trend of physician training offers bleak promise. One might add that the acute shortage of trained medical, psychiatric, and paramedical workers in public institutions is a national disgrace, as is the lack of reasonable accommodation and proper care for the chronically infirm. In the face of such knowledge it may seem odd that professional medical associations continue to agitate against expansion and to restrict opportunities for medical training and panel practice. However, it seems odd only until we begin to appreciate the significance of very high medical incomes (in relation to those of other professions requiring comparable training), the rapid advancement of fee schedules, fee-splitting arrangements between practitioners and specialists, and the custom among hospital specialists of holding out for a good percentage of the hospital's take. It is not really odd so much as it is lamentable.

What really is odd is Harris' repeated assertion that the physician "is often embarrassed by his high incomes." Should this be true, it is an embarrassment easily avoided. On the contrary, other studies have indicated that high income is a prime attraction for a majority of medical school candidates; and arrangements for salaried practice have been consistently (and often maliciously) opposed by medical associations on the ground that salary impairs "incentive"—presumably, the incentive to make a fast buck.

Harris' analysis shows that hospital expenditures have risen since World War II by something like  $2\frac{1}{2}$  times the rise in personal disposable income, and that hospital prices have risen by about three times the rate of all consumer prices. These are attributed largely to wage increases, costly innova-

tions for advanced therapy, increasingly expensive education and research, regional maldistribution of hospitals (paralleling maldistribution of income), and the relative increase in small and more costly hospitals. Divided responsibility in hospital administration is also regarded as contributing to "low productivity." With the drying up of philanthropy (about nine-tenths of total hospital revenue now comes from patients), U.S. hospitals face a dilemma similar to, albeit of lesser degree than, that facing Britain's hospitals before the War. British hospitals were saved by the National Health Service, while ours are being "bailed out" with insurance; although, on balance, the English solution would appear more humane. U.S. hospitals are still confronted by the perennial decision of how many indigents to turn away, when Victorian rules of eligibility enable local welfare authorities to avoid paying for their care.

The chapter on the British National Health Service reveals, for those not already aware of it, that NHS has successfully met Britain's medical needs to a degree unknown in the United States, and that it enjoys the full endorsement of all major professional associations (as do the compulsory programs in Scandinavia and elsewhere). Harris might also have noted that such compulsory government-financed programs operate at much lower cost than the U.S. system, both in terms of relative administrative expense and of the proportion of GNP required for adequate coverage.

There is an interesting chapter on the pharmaceutical industry (drawn largely from the 1961 Kefauver Subcommittee hearings), except for Harris' contention that "To encourage research, patent rights are necessary." Surely it is general knowledge that drug patent rights are commonly obtained by means unassociated with discovery, and that the discoverer is seldom the chief beneficiary of the patent on his drug. There is nothing to indicate that research has been less significant in countries with little or no patent protection; while, on the other hand, the history of U.S. patents in some drugs is fraught with restriction to competitive enterprise, interference suits leading to market-sharing among the litigants, and intense political pressures or cartel arrangements tending to internationalize the existing pattern of very high domestic concentration in the drug industry.

The serious student of medical economics will find this book disappointing. All of the statistical data antedate those in the more trenchant and comprehensive works already on the market; there is, for example, no significant addition to the excellent study by Somers for Brookings four years ago, despite the availability of more recent data. The newcomer to the subject will find the book provoking for its display of limited imagination (such as the old saw that health insurance induces claims, without mentioning the necessary precondition that coverage be less than comprehensive) as well as for its unmoving conclusions (that some solution must be found for the difficult problems that exist, and that government should subsidize free-enterprise medicine more heavily). It is a source of wonder that Harris never faces up to any practical solution for ending our exploitation of the sick.

He refers to Chapter 2 of his book as "largely statistical and hence dull."

Actually, Chapter 2 is no worse than the rest; they are mostly dull and show little evidence of revision since the day they went through the dictating machine. They are further labored by awkward metaphors (such as "the skyrocketing of incomes of physicians") and by habitual abbreviation of common phrases, such as "institutions of higher learning (IHL)" even on those occasions when the reference is not repeated.

## VACANCIES AND APPLICATIONS

The Association is glad to render service to applicants who wish to make known their availability for positions in the field of economics and to administrative officers of colleges and universities and to others who are seeking to fill vacancies.

The officers of the Association take no responsibility for making a selection among the applicants or following up the results. The Secretary's office will merely afford a central point for clearing inquiries; and the *Review* will publish in this section a brief description of vacancies announced and of applications submitted (with necessary editorial changes). Since the Association has no other way of knowing whether or not this section is performing a real service, the Secretary would appreciate receiving notification of appointments made as a result of these announcements. It is optional with those submitting such announcements to publish name and address or to use a key number. Deadlines for the four issues of the *Review* are February 1, May 1, August 1, and November 1.

Communications should be addressed to: The Secretary, American Economic Association, 629 Noyes Street, Evanston, Illinois. 60201.

### *Vacancies*

*Labor economists and/or statisticians:* The measurement of the economic damages suffered by those who are wrongfully injured or killed is a new area for the application of economic and statistical knowledge and research techniques. This field has been pioneered successfully and Associated Appraisers of Impaired Earning Capacity is now providing this service to attorneys on a nationwide basis. Those in it appraise the losses and are required to testify as an expert in court trials and must withstand hostile cross-examination. It is one of the highest-paid forms of work in the profession and it is possible to engage in it as a part-time activity. Requirements: (1) minimum status of associate professor; (2) experience in research in collective bargaining agreements and fringe benefit programs; (3) location in or near major metropolitan area. Send résumé and list of publications to: Philip Eden, President, Associated Appraisers of Impaired Earning Capacity, 1303 Walnut St., Berkeley, Calif. 94709.

*Economists and Econometricians:* We seek several outstanding men or women for the professional staff of a small management consulting firm whose principal clients are blue-chip industrial companies. Postgraduate training in economics at a leading university and several years' experience in business, consulting, or teaching required. New York City location. Ten per cent travel. Salary open and depends on qualifications and previous achievements.

P290

*Micro- and macrotheory; urban and regional economic development:* Need a person in each of these areas. Candidate with Ph.D., preferably with experience. Salary with minimum experience about \$8,500 for nine months. Employment during one of two five-week summer sessions usually available. Municipal university located in urban midwest. Opportunity for research. Liberal fringe benefits. Opportunity to teach a graduate course (M.A.) level. Twelve-hour teaching load, of which one-fourth must be taught after 4:00 P.M. Applications and credentials may be sent to: Dr. E. J. Steele, Economics Department, Omaha University, Omaha, Nebraska.

*Economist:* Two positions open. \$9,096 to start; 5 per cent annual increments to \$11,616. Master's degree in economics or regional science, plus 4 years of responsible research experience or an equivalent combination of experience and training. Ph.D. in economics or regional science with emphasis on econometrics may be substituted for two years of experience. One year of research utilizing econometric techniques in development and use of regional input-output tables and economic models may be substituted for two years of general research experience. Position 1: With Research and Analysis Division of Department of Planning and Economic Development, State of Hawaii, to conduct research, prepare detailed reports, make recommendations relating to revision of State General Plan and achievement of State's economic goals.

## FOREWORD

The two essays appearing in this supplement of the *American Economic Review* are the first of a series of papers recounting and assessing post-war developments in economic thought in leading professional centers where English is not the conventional language in use. This venture was made possible by a grant by the Ford Foundation to the American Economic Association. The Committee is pleased to make these essays available to the membership.

In extending our invitation, the Committee asked each author to consider whether the impact of postwar policy problems had been significant to the development of thinking and research, or whether the evolution of professional work had taken a more detached course. We also urged him to concentrate upon a few major themes. Notwithstanding these suggestions, each author was given full freedom to develop his topic as he envisaged it. In consequence, each essay represents his personal judgment of what he considers to be the important developments in thought in the country or region with which he is concerned.

Unfortunately there is no word corresponding to "Anglo-Saxon" which covers the German-speaking countries and regions. Even the Northern European countries with their different languages can be conveniently grouped under the title "Scandinavian." No such shortcut is open to the reviewer of literature written in German. Though most of the writing naturally comes from Germany, accuracy would require the constant use of such clumsy phrases as "economic theory in Germany, Austria, and Switzerland" or "economic theory in the German-speaking countries." To simplify matters I shall be less exact and let the word *German* frequently stand for developments in all three countries.

A second complication arises from the division of Germany into two parts. In this article, only the literature of West Germany is taken into

account. East Germany has also produced a considerable amount of economic literature since World War II, but since research there is predominantly on Marxist lines and is closely linked to the discussions going on in the Soviet Union and Eastern Europe, its presentation is best suited to a study of theoretical developments in the socialist countries.

Needless to say, nothing like a complete review of German economics will be aimed at. Limitations of space and of the author's knowledge alike rule out any such attempt. All that can be hoped for is a sketch of some of the major trends—old and new—which influence current economic thought in the German-speaking countries. The choice of authors and books to illustrate my points is necessarily somewhat haphazard, but it is hoped that in the end the reader will have gained some feel of what is going on in this part of the world.

### I. *The Advance of Macroeconomics*

It would be much easier for the reviewer of current economic thinking in Germany, Austria, and Switzerland to arrange his material if there were any clear-cut "schools" that originated in these countries in the postwar period. At the turn of the century the "Austrian school," the German "historical school," the "Kathedersozialisten," the intense Marxist controversy (outside the universities) would have provided obvious starting points for a panorama of German economic theory. Today there are no such definite German "schools," neoliberalism perhaps being the only exception. But neoliberalism has—as we shall see later—little to offer in the field of economic theory that is new. The main stress of the neoliberal writings lies on programmatic aspects.

The difficulty of detecting any special German schools may be partly a matter of time. I do not know how long the Austrian school or the Swedish school actually existed before they were clearly perceived as separate groups. It is certainly easier to find the common ground of different and differing writers in retrospect than during the process of "school" formation. Furthermore, present day circumstances are not conducive to the existence of a multitude of different schools. First, economic debate is far more world-wide today than it used to be (with Anglo-Saxon publications playing a leading and unifying role), leaving less room for national and regional enclaves. Second, economic theory is getting more and more specialized and departmentalized, and this reduces the scope for grand methodological line-ups.

Even so the dim outlines of some special theoretical groups can be discerned in the postwar world. One could think of the sociological approach of some French authors, of the "Chicago school," of the Tinbergen group in the Netherlands, the Ragnar Frisch group in Norway, and others. I doubt whether it would be fruitful to try to discover the

nucleus of some such special schools in postwar Germany. Typical of postwar German economics has been a broad stream of economic writings covering a very wide field of interests and methods. This stream combines contributions from various sources and differing traditions. It is the special *mixture* of past and present strands of thought going into current research that gives German economic literature its own distinct character. By tracing some of the major influences on present-day German economics, I hope to provide a preliminary glimpse of a vast, and not easily digestible, field.

The years of fascism and still more those of war—twelve rather decisive years in the development of Anglo-Saxon economic theory—left German economic theory isolated from the big discussions that spread so quickly from Keynes' Cambridge to the English-speaking and Scandinavian countries. This was necessarily so in Germany and Austria, which for political reasons were more or less cut off from the ideological currents in the democratic countries. But to some extent it also applied to Switzerland, where no such *political* impediments existed. The influence of German traditions was strong enough to let the new economics filter through only slowly.

A good example is the first volume of Walter Adolf Jöhr's extensive work on the theoretical foundations of economic policy which deals with the problem of perfect competition and which appeared in St. Gallen in 1943 [28]. Jöhr, who had spent some months in Harvard and Chicago, includes in his work all the important results of Joan Robinson, E. H. Chamberlin, and R. Triffin on competition and monopoly; but they are so imbedded in basic remarks about the economic order, in numerous metaphysical and psychological asides, and in all sorts of additional economic considerations that the difference between this and a contemporary English book on the same subject is at once obvious.<sup>1</sup> The difference becomes the more noticeable when we look at the second volume of Jöhr's large work which appeared nine years later [29]. In this comprehensive (700-page) study of the trade cycle, which can stand comparison with G. Haberler's celebrated work, we still find a comparatively large part devoted to older and now mostly neglected German sources; but the breakthrough of the new theories that had taken place in the meantime is evident. In addition to J. A. Schumpeter, we find Keynes, Hansen, Harrod, Hicks, and Samuelson among the most frequently quoted authors.<sup>2</sup>

<sup>1</sup> I do not mean to pass judgment on the relative merits of the two kinds of approach. All I want to stress is that in those days the "new economics," though not inaccessible to the Swiss, had not made much imprint on their leading works.

<sup>2</sup> While Jöhr gives full account of the various "mechanistic" trade cycle theories in vogue, he himself inclines toward a "non-deterministic" psychological theory. He draws particular attention to certain aspects of mass psychology which he regards as a decisive force in the cumulative processes of the cycle.

In some cases Swiss writers *did* join the bandwagon of "modern" macroeconomics and econometrics at a rather early period with interesting and critical contributions.<sup>3</sup> But, on the whole, these were exceptions and it remains true that Switzerland, not much less than Germany and Austria, remained comparatively unaffected by the winds that were blowing so strongly beyond the Channel and the Atlantic. In a review of Alec Cairncross's *Introduction to Economics* [11], written after the war, Emil Küng could still say that this book and Benham's *Economics* are "an excellent introduction into the economic way of thinking at present practiced in the Anglo-Saxon countries which is bound to have a growing influence on Switzerland—and not to the country's disadvantage" [64, p. 666].

When the war was over, the door was opened in Germany and Austria to an influx of the new ideas. What had been developed rather organically in long drawn-out discussions in Britain and America could now pour in rather suddenly in its semi-finished or finished forms. There was, to begin with, little time for a process of sifting and mixing. Different streams of thought rolled on side by side, connected by few and unsatisfactory communication systems.

The entry of the new economics demanded first of all rather wide surveys in order to enable the students and the younger economists to get a general view of the existing state of modern economic theory as it had developed outside Germany and, in particular, in the Anglo-Saxon and Scandinavian countries. At this stage, textbooks had a more than ordinary function to fulfill.

Two texts which came out rather soon after the war did play a decisive part in spreading the new economics. On a more elementary level, Andreas Paulsen's introduction to Keynes [43] gave numerous students and interested laymen the first extensive and reliable (though not quite systematic) survey of Keynesian and post-Keynesian economics. On a quite different level, we find the three-volume *Introduction to Economic Theory* by Erich Schneider [52]. Now in its eighth edition with improvements and revisions constantly being made, this work represents one of the best introductions to modern economic analysis available, not alone in the German language but quite generally. Schneider, who has taught in Denmark as well as in Germany, is able to blend Scandinavian and German contributions with the substance of contemporary Anglo-Saxon theory and to present it in a lucid style, supported but not displaced by mathematics and geometry. His text has helped the students of the postwar years to enter "into the

<sup>3</sup> See, for instance, H. G. Bieri, *Die neuen Konjunkturtheorien von Keynes, Hawtrey and Ohlin in kritisch vergleichender Betrachtung*. Wollishofen 1944, or the contributions by H. Bohl and H. Dutschler in *Konkurrenz und Planwirtschaft*. Bern 1946.

secrets of macroeconomic dynamics,<sup>4</sup> a generation of students which in the meantime has moved into leading positions in national and international statistical offices, in the civil service, and in research institutes" [8, pp. 218-19].

A short sketch of the structure of this work (as it presents itself in its later editions) may not be out of place. Like J. R. Hicks in his *Social Framework*, Schneider introduces his reader to economics by giving him a view of the interdependence of the whole system. This is the subject of the first volume. The process of national income formation is thoroughly described with the aid of "social accounting." Current methods of representation are generously used: national accounting, equations, flow diagrams, and input-output tables. Earlier macroeconomic approaches—Quesnay, Marx—are brought in for comparison. In the end the reader is familiar with the important formal relationships among the basic macroeconomic aggregates. The second volume deals with the traditional subject of microeconomic statics. The theory of demand is derived with the aid of indifference curves, and a linkage between the micro- and macroeconomic consumption function is established. The theory of production, often neglected in textbooks, is well developed, not least because this is a field in which Schneider has been actively engaged for many years.<sup>5</sup> Next the different varieties of competition and monopoly and the revenue plans of the firms are discussed. This leads to a treatment of the demand for factors of production. Price theory (including interest theory where the liquidity preference and loanable funds theories are combined) is at first developed from selected partial equilibrium cases, while the final chapter of this volume closes with an extended version of (Walrasian) general equilibrium. (The extension does away with Walras' full employment assumptions.) The third volume brings together the threads of the first two volumes. After an exposition of money and its functions, a discussion of the dynamics of the whole system is presented, first in a purely private economy, later with special attention to government activities. The instruments of modern employment, trade cycle, and growth theory—multiplier, accelerator, consumption and investment functions, and the like—can here be sampled and critically examined.

While modern economics thus entered postwar Germany early, it certainly did not dominate the field. More traditional lines of thought did

<sup>4</sup> I prefer to translate the German word "Kreislauftheorie" somewhat freely in this way rather than with the more verbal but clumsy "circular flow theory."

<sup>5</sup> Apart from several articles, see his *Wirtschaftlichkeitsrechnung*, Tübingen 1952, and *Industrielles Rechnungswesen*, 2d ed. Tübingen 1954. The latter book had already appeared before the war but was greatly extended in the postwar edition.

not just fade away but continued to exist. In the textbook field one should name: Alexander Mahr's *Introduction* [37] which is based on the Austrian marginal utility school (particularly in the refined shape it obtained after Menger and Böhm-Bawerk in the hands of Friedrich von Wieser and Hans Mayer), with value, prices of final goods, and derived demand ("imputation") for factors of production providing the backbone of the investigation;<sup>6</sup> Hans Ritschl's two-volume work on economic theory [46] with its roots firmly based in the historical school and in metaphysical traditions ("... the individual is ethically autonomous, he is as a body-soul-being an entity, directly related to God,") or Erich Carell's much used textbook on traditional lines [12].

This rather sudden confrontation of different fully established theoretical approaches naturally created some heat, and some clashes of opinion were more passionate and more of the "either-or" type than they could have been in the Anglo-Saxon world in this period. A good example—though in the sharpness of its tone not quite typical—is the essay on Keynes' theory by Hans Mayer (d. 1955) [39]. Mayer attacks all along the whole line. He mixes well-deserved criticism (not all of it new) of some of Keynes' ambiguities and conceptual weaknesses with rather irrelevant quarrels about words and definitions. In some cases he fights more against Keynes' empirical assumptions than against the underlying theory (e.g., do workers aim predominantly at a money or a real wage?); in other cases he dismisses Keynes' contributions (multiplier, etc.) as "old tools." The system as a whole is, therefore, somewhat lost from view. Mayer's main charge, however, is directed against the big aggregates. In the change-over from microeconomics to macroeconomics he sees a return to mercantilism. Thus he regards Keynesian theory—its method, structure, and results—as a retrogressive step.<sup>7</sup>

Mayer's attack and similar views expressed by some other writers (Röpke, Hahn, Adolf Weber) drew a spirited reply from Erich Schneider [54, 89 ff.]. In just over thirty pages he presented a con-

<sup>6</sup> It is, however, significant for the "spirit" of the intervening years that the second, greatly extended edition of Mahr's textbook, *Volkswirtschaftslehre*, Wien 1959, has partly lost its predominantly Austrian character and includes macroeconomic and growth problems.

In current research there have been few attempts to revive the earlier utility and value discussions of the Austrian school. A notable exception is the book by L. Illy-Schönfeld (d. 1952), *Das Gesetz des Grenznutzens*, Wien 1948. See also the two articles by Mahr, "Das Gesetz vom Grenznutzenniveau im Lichte der Kritik" in *Neue Beiträge zur Wirtschaftstheorie, Festschrift anlässlich des 70. Geburtstages von Hans Mayer*, edited by A. Mahr, Wien 1949, and "Indifferenzkurven und Grenznutzenniveau," *Zeitschrift für Nationalökonomie*, 1954, 14, 325 ff., in which the indifference curve approach is sharply attacked. For a critical reply see W. Krelle, "Die 'Neue Österreichische Schule' in der Nationalökonomie," *Jahrbücher für Nationalökonomie und Statistik*, 1953, 165, 454 ff.

<sup>7</sup> *Op. cit.*, p. 50.

densed defense of all the major aspects of Keynes' methods (not necessarily of his conclusions) culminating in a plea to abolish the artificial line between "old" and "new" economics.

One other case of such a full-scale controversy concerning an entire branch of modern economics may be cited. In 1954 Werner Hofmann published his book on national income accounting [27]. The postwar practices of national income calculations and the economic interpretations surrounding them are rejected lock, stock, and barrel. Here again a well-placed scepticism and a critical insight into some of the superficialities of the national income conventions are curiously mixed with inflated trivialities and downright misunderstandings. The rationale of the total procedure never becomes clear and the possibility for a balanced judgment is correspondingly reduced. Here again it did not take long for an extensive and fundamental reply to appear.<sup>8</sup>

While in the heat of these earlier critical attacks some arguments went badly astray, they, nevertheless, fulfilled a certain purpose. They served as an antidote against too uncritical an acceptance of some of the imported ideas—the opposite danger from that of complete negation. Gradually the critical attitude toward the "new" became both informed and less agitated. No longer did one think that one could completely destroy this or that theoretical system by a single pungent article. The treatment became longer; more space was given to exposition and judgment. In this field we may mention the books by Wilhelm Weber and Albrecht Forstmann [61] [18]. The latter book in particular, though no doubt rather hostile to Keynesianism in its basic attitude and not free of serious misinterpretations, presents an impressive array of the international macroeconomic literature up to the date of its publication.

Today, though differences in emphasis still exist, the acute controversies have largely died down. The new economics has been absorbed—at least to some extent—by a growing number of economists. Indeed one could almost say of 1960-German economics what Samuelson had said ten years earlier of American economics: "In recent years 90 per cent of American economists have stopped being Keynesian economists or anti-Keynesian economists" [48]. This is best seen by glancing through the leading theoretical journals of Germany, Austria, and Switzerland. Types of subject and methods of approach differ little from what one is used to finding in Anglo-Saxon journals.

If we take growth theory as an example of one of the most fashionable recent developments in the Keynesian (or macroeconomic) tradi-

tion, Germany certainly stands the test of the time. There is a constant flow of contributions to this field. Erich Preiser tells us that two out of three manuscripts which he receives as coeditor of the oldest German economic journal deal with problems which belong in the sphere of growth theory [45, p. 119]. So far, German theory has not been able to add any fundamental or highly original works to this field, although there have been several interesting improvements in one detail or another.<sup>9</sup> But perhaps the most succinct and the most extensive exposition of growth economics can be found in German literature. In 1953 Gottfried Bombach wrote an informative article on growth theory [9, 110 ff.], which beautifully presents the origin, the essence, the structure, and the limitations of Harrod-Domar-type growth models.<sup>10</sup> At the other end of the scale is Sigurd Klatt's volume on the theory of industrialization [30] where we find—gathered around the theoretical structure provided by Harrod, Domar, Hicks, Colin Clark, and others—an extensive treatment of the incentives to economic growth, of the growth process itself, and of the elements making for stagnation. Here practically no niche of growth theory remains unlighted, no point untouched. The text runs over 430 pages, followed by 90 pages of systematic bibliography and an authors' index of 17 pages containing some 1400 names (my rough estimate). If ever Germany's reputation for thoroughness should be in danger, here—at least for the field of growth economics—is ample proof of its continued existence.

## II. *German Pioneers of Modern Macroeconomics and National Income Analysis*

One consequence of the force with which the voluminous Keynesian literature poured into postwar Germany, Austria, and Switzerland was

<sup>9</sup> As an early example one could name W. G. Hoffmann (Walther Hoffmann, not to be confused with the earlier mentioned Werner Hofmann), "Wachstumsprobleme offener Volkswirtschaften," *Schweizerische Zeitschrift für Volkswirtschaft und Statistik*, 1950, 86, 498 ff., where the special problems of an open economy under growth conditions are stressed. These had been rather neglected in the earlier discussions.

<sup>10</sup> At this point we may mention that longish articles like this (the Bombach article runs over 56 pages), covering the results of recent research for a whole subject, have appeared from time to time in some of the German journals and have to some extent filled the need which in the Anglo-Saxon world has been met after the war by the two *Surveys of Contemporary Economics* and is currently being satisfied by a series of survey articles appearing in the *Economic Journal* and in the *American Economic Review*. In addition to the above mentioned article by Bombach, we have among these comprehensive surveys another contribution from the same author, "Kreislauftheorie und volkswirtschaftliche Gesamtrechnung" (Circular flow analysis and national income accounting), *Jahrbuch für Sozialwissenschaft*, 1960, 11, 217 ff.; further, A. Predöhl, "Neuere Literatur zur Aussenwirtschaft" (Recent literature on international trade), same journal, 1959, 4/10, 80 ff.; K. D. Kuhlo, "Eine Analyse des Vollkostenprinzips" (An analysis of the full cost principle), *Weltwirtschaftliches Archiv*, 1955, II, 75, 137 ff.; and several others.

that important and original German contributions to macroeconomics were somewhat neglected. In fact, the search for a new macroeconomic approach originated in Germany almost thirty years ago. Two pioneers set out to develop macroeconomic *Kreislaufmodelle* (circular flow models): Ferdinand Grünig (d. 1960) and Carl Föhl. It is perhaps no accident that both started their careers as engineers, changing over to economics later in life. Their macroeconomic dynamics are obviously influenced by analogies from technical flow processes. As with Keynes, their interest in the mechanism of the macroeconomic process was roused by the Great Depression of the thirties.

Grünig started to write his book on economic flows—the flow of goods and the flow of money—in 1931; it was published in 1933 [20]. In it he developed a model analysis (by no means usual at that time) which contained all the terms of modern employment theory, though not in the brilliant form it received by Keynes. Here we find already the equation showing the equality between (ex-post) saving and investment, the recognition that purchasing power is a function of the level of production, the idea of the multiplier, and the possibility of underemployment equilibrium. Grünig's book did not only deal with theory; from the few statistical sources available at the time he also constructed national accounts for the German economy for the years 1929 and 1932. His policy conclusions were that in a noninvesting economy—Germany in 1932—the growth of savings is harmful. Public investment should be increased and the building of private homes and agricultural improvements should be fostered. He also tried to work out, with the aid of his model, the full quantitative primary and secondary effects of such actions.

On a far more sophisticated level, in its theoretical standing quite on a par with Keynes' *General Theory* we have Föhl's book on money and the macroeconomic process.<sup>11</sup> From its structure, most Keynesian and several post-Keynesian developments can easily be deduced. Like Keynes, Föhl laid bare the necessary relationships between important macroeconomic aggregates—saving, consumption, investment, production, incomes; like Keynes, he introduced a consumption function and an investment function; like Keynes, he saw the demand for cash (and not the demand for savings) as the regulator of interest rates.

But there are, of course, also significant differences. It is a curious thing that Föhl keeps in his analysis a greater formal continuity with Keynes' *Treatise on Money* than did Keynes in his *General Theory*. Throughout his book, Föhl distinguishes between firms and their fac-

tors of production. Income flow is divided into factor incomes and residual (windfall) profits (depending on the difference between investment and factor savings), and total income becomes equal to consumption expenditure of firms plus consumption expenditure of factors plus savings of factors. This higher degree of disaggregation leads to a more useful investment function which in Föhl's case is not only dependent on the rate of interest but also on profits. Föhl's theory of the rate of interest is less dependent on underemployment conditions than is Keynes': he stresses that under full employment it may have to be brought into line with the state of the labor market. On the other hand, Föhl did not fully develop the multiplier process, and he is on the whole less sure of his subject than Keynes when it comes to questions of the monetary and banking mechanism.

Föhl's exposition is very different from that of Keynes. He is more difficult to read; he does not have Keynes' elegance of style. On the other hand, Föhl made ample use of ingenious circular flow diagrams which forced on him (and the reader) a degree of rigor which was sometimes lacking in Keynes' argumentation.

As we said before, the impact of Grünig's and Föhl's early attempts on German economics was limited and has been partly swamped by the reception of the richer Keynesian and post-Keynesian literature. Originally their influence was hampered because being outsiders and using untraditional forms of analysis they remained for a long time unnoticed by a large part of the profession. But the interest in macroeconomic flow models which they had kindled did not die down, and there has been, in the past twenty-five years, a constant trickle of important contributions. In this context one should mention Hans Peter (d. 1959) who developed interesting static and dynamic mathematical models of the circular flow process [44]. The engineering origins of German circular flow analysis enabled German economists to meet with mathematicians and physicists to discuss the analogies between economic and technical control processes.<sup>12</sup> While there is a danger that analogies of this sort are driven too far and lead to a disregard of the sociological aspects of economic life—already far too much neglected in non-Marxian economics—there is no doubt but that they contain considerable heuristic possibilities.

The full logic of the circular flow thinking has recently been directed to a greater extent to monetary flows. While statisticians in the United States and elsewhere are struggling more or less successfully to provide

the data for a watertight flow-of-funds analysis, there are still many problems of definition, consistency, and operational relevance to be solved. German theorists, it would seem, will take an active part in these discussions.<sup>13</sup>

### III. *Monopoly and Competition*

So far we have spoken of the new economics mainly in terms of Keynesian and post-Keynesian developments. If we stretch the term to include the "monopolistic competition revolution," the situation in German economics is quite different from the one pictured earlier with regard to the Keynesian debate. In this field, no large-scale import of foreign ready-made results was required. From the very start of the new value theory, German writers have produced numerous and original contributions to the discussion. Even before Chamberlin and Joan Robinson had published their treatise did an attempt at a more sophisticated classification of market behavior appear in a German journal [57, 761 ff.]. The attempt had several shortcomings and did not come off. In subsequent years, however, some of the leading German economists entered the market-form debate—Heinrich Stackelberg, Erich Schneider, Walter Eucken.<sup>14</sup> Since then the chain of writings on monopoly and competition has never been broken.<sup>15</sup> While this voluminous literature has touched almost every aspect of monopolistic competition and oligopoly theory, too much weight has probably been given to problems of classification. Like the connoisseur of a large butterfly collection, economists have tried to put their different (market) types into some perfect systematic order. What baroque forms twenty-five years of filigree work have produced can best be judged from the following table which is taken from the book by Ott cited in the previous footnote.<sup>16</sup>

<sup>13</sup> An important contribution is W. Stützel, *Volkswirtschaftliche Saldenmechanik. Ein Beitrag zur Geldtheorie*, Tübingen 1958.

<sup>14</sup> H. Stackelberg, *Marktform und Gleichgewicht*, Berlin 1934; E. Schneider, "Zur Konkurrenz und Preisbildung auf vollkommenen und unvollkommenen und unvollkommenen Märkten," *Weltwirtschaftliches Archiv*, 1938 II, 48, 399 ff.; W. Eucken *Die Grundlagen der Nationalökonomie*, Jena 1940. All these authors have also later contributions to their names.

<sup>15</sup> Here is a random selection of some recent contributions: A. Ott, *Marktformen und Verhaltensweise*, Stuttgart 1959; H. Lampert, "Die Preisfuhrerschaft. Versuch einer zusammenfassenden Darstellung," *Jahrbuch für Nationalökonomie und Statistik*, 1960, 172, 203 ff.; E. Heuss, "Das Oligopol, ein determinierter Markt," *Weltwirtschaftliches Archiv*, 1960, 84, 165 ff. This may be the appropriate place to mention Krelle's very comprehensive book on all conceivable aspects of price theory (W. Krelle, *Preistheorie*, Zürich und Tübingen 1961).

<sup>16</sup> A. Ott, *op. cit.*, p. 16. Ott himself is not just a "classifier." In his book he tried to achieve a synthesis between what he calls the "morphological" (number of sellers, etc.) and the "behavioristic" (elasticities, cross-elasticities, game theory) theories of market forms.

#### IV. *Traditional Influences and Influential Traditions*

As mentioned earlier, present-day economic research in Germany, Austria, and Switzerland no longer differs greatly from research activities in the Anglo-Saxon world. But while the type of questions asked and the methods used are similar, it would be strange indeed if past traditions did not color to some extent the total *oeuvre* of German economists. What, then, are some of these distinguishing features?

First, we have the influence of the historical school and of a whole list of prominent writers of the past (Marx, Max Weber, Sombart, Oppenheimer, Weiser, Schumpeter) who never rested content with pure economics, but always aimed at a blend of economic and sociological theorizing and—if necessary—ventured pretty far into the neglected fields of sociology and social psychology. Though some of them were regarded as outsiders by the main stream of academic economists they were not without influence. In this respect, German economics resembles somewhat the American situation, where Veblen and institutionalism played a similar (though less important) role; there are fewer points of contact with England where developments of this sort were the exception.

A definite historical school, which tried to draw on all aspects of history and civilization, no longer exists, but the spirit of this school is clearly visible in some writings. Here we could name Edgar Salin<sup>17</sup> who, significantly, has written not only on economics but also on politics, philosophy, and poetry. Also in the historical vein are some of the economic publications of the List-Gesellschaft, which are edited by Salin and Erwin von Beckerath.

More widespread than the survival of a predominantly historical approach is an alertness to sociological factors, a realization that the neglect of *exogenous* circumstances may falsify the *pure* economic picture. Good examples in this direction are Erich Preiser's excellent contributions in the field of distribution theory<sup>18</sup> where he shows the influence of property on the formation of incomes. He stresses that the institution of private property has been neglected vis-à-vis the problem of market forms (monopoly, monopsony), although it has equal or even stronger effects on the demand and supply situation of the factors of production. With this point in view, the whole marginal productivity theory acquires a different and more limited meaning. In this direction, too, are some of Josef Dobretsberger's studies on monetary problems which are written with a strong sociological and institutional slant.<sup>19</sup> In the Schumpeterian tradition there is also no inhibition to cross the border and write a critical analysis on predominantly sociological themes.<sup>20</sup> Again, a comparison of the previously mentioned work by Jöhr on the trade cycle<sup>21</sup> (which draws on German as well as on Anglo-Saxon sources) with an English or American text on the same subject reveals greater stress in Jöhr's volume on extraeconomic factors.

<sup>17</sup> See, for instance, his booklet (based on an article in *Kyklos*, 1955, 8, *Ökonomik der Atomkraft. Vor einer neuen Etappe der industriellen Revolution*, Köln-Marienburg 1955) where he roams over past and present tendencies in the energy sector in order to answer the question (affirmatively) whether the industrial revolution and mankind have entered into a new era.

<sup>21</sup> See above, p. 3.

Another German speciality of bygone days was an excessive interest in methodological questions. While for a long time problems of method probably received too little attention in the pragmatic Anglo-Saxon literature, some German books were in danger of burying their theoretical analysis under a mountain of methodological considerations. The heat which methodological controversies could create was best illustrated by the bitter dispute between the historical and the Austrian school (particularly between Schmoller and Menger) in the 1880's, which belongs to the classics of German economic polemics.

In recent decades, the extreme preoccupation with methodological questions has subsided. Now books on economics can be and are written without lengthy reflections on the appropriateness of the methods chosen. Yet a healthy interest in methodological problems has survived. Occasionally there are still reflections of the not very fruitful *either-or* type (inherited from Sombart's days): whether economics is an *understanding* (verstehende Wissenschaft) or a quantitative science. But on the whole the interest of the methodologists has moved to newer problems, posed by recent developments in the fields of philosophy and economic research. In these writings—which have their counterparts in Anglo-Saxon specialist literature and which owe a good deal to Myrdal's pioneer work—we find a greater awareness of the ideological trappings in much of the received doctrine and an endeavor to lay the methodological basis for a more empirical economic theory. This occasionally links up quite naturally with a demand for an increased consideration of sociological factors in economic theory.<sup>22</sup> With the new forms of economic models gaining in importance, increasing attention has been given to the question of how far the use of mathematics is justified.<sup>23</sup> Full agreement in these discussions is, of course, not to be expected, because of differences in training, tradition, field of study, and the like.

Closely related to the problem of method is the question of (ethical) value judgments in economics which has been haunting German economists ever since Max Weber demanded that economics should be *wertfrei* (at least when economists speak *qua* economists). Though much has been written on this subject in the past, the discussion is still continuing. While most writers probably accept Weber's position that economic theory should be restricted to a detached investigation of

<sup>22</sup> In this direction see the interesting contributions by Hans Albert, in particular his *Ökonomische Ideologie und politische Theorie*, Göttingen 1954, and "Nationalökonomie als Soziologie," *Zur sozialwissenschaftlichen Integrationsproblematik*, *Kyklos*, 1960, *XIII*, 1 ff.

<sup>23</sup> Two recent attempts at an evaluation of the scope and usefulness of mathematical methods are G. Kade, *Die logischen Grundlagen der mathematischen Wirtschaftstheorie als Metho-enproblem der theoretischen Ökonomik*, Berlin 1958, and H. W. Brand, *Über die Fruchtbarkeit mathematischer Verfahren in der Wirtschaftstheorie*, Frankfurt a.M. 1959.

what *is* and not of what *ought to be*,<sup>24</sup> there are others who believe that there are immanent values in the economic process which can be detected by the economist, enabling him to use the adjectives *good* and *bad* in an objective sense.<sup>25</sup> Still others stress that present-day economics is so loaded with hidden valuation problems that scientific objectivity will be best served, not by a complete prohibition of value judgments, but rather by a conscious and critical exposition of the chosen value basis by the economist [6, 26 ff.].

Whatever the economists' attitudes (if any!) to this problem may be in principle, in actual practice they tend (almost necessarily, I believe) to pack value judgments into and between their lines—today as much, if not more, than ever. This is most prominent in the way problems are chosen or left out of consideration, but direct value pronouncements are also not infrequent, and this tendency has expanded along with the general cold war atmosphere. Free markets, economic integration, and other targets of official economic policy are often uncritically accepted (explicitly or implicitly) as higher aims, desirable in themselves and beneficial to *all* classes of society. It may be fairly easy to find angry young men in German belles-lettres; among economists they are very rare indeed. But this is probably not a specific note of German economics.

Since the turn of the century German economics has known a rather sharp division between *Volkswirtschaftslehre* and *Betriebswirtschaftslehre* (political economy and business economics, respectively). The great expansion of theoretical economics (teaching and research) after World War II has led to a similar growth in the sector of *Betriebswirtschaft*. But the difference between the two disciplines, always rather thin at the edges, is becoming more and more blurred. On the one hand linear programming, input-output analysis, and similar developments in economic theory have pushed *Volkswirtschaftslehre* nearer to production problems of individual industries and plants; on the other hand, some *Betriebswirtschaftler* (business economists) are expanding their theoretical apparatus, assimilating it with the models used in *Volkswirtschaftslehre*. This leads to books which cannot be easily placed in one category or the other, as for instance the excellent book on production and selling by the *Betriebswirtschaftler* Gutenberg [21], which could

<sup>24</sup> For a full discussion of the evolution of this view see Wilhelm Weber and E. Topitsch, "Das Wertfreiheitsproblem seit Max Weber," *Zeitschrift für Nationalökonomie*, 1952, 13, 158 ff. It is realized that a valuation process creeps in: (a) in setting the aim of a "value-free" economics, and (b) in the choice of subjects. The introduction into the analysis of valuations by other persons *as data* is, of course, not objected to.

<sup>25</sup> This view, which in the interwar years had been most consistently pressed by the German economist Gottl-Ottlienfeld, is for instance taken by T. Pütz, *Theorie der allgemeinen Wirtschaftspolitik und Wirtschaftslenkung*, Wien 1948, Chs. I, II, and IV.

equally well serve as a first-class text on the theory of the firm in a course on economic theory.

I want to conclude this section with the one specific German aspect in economics which is not so much a remnant of long-standing traditions and influences, but rather the outcome of recent growth. I refer to the school of neoliberalism (ORDO-liberalism, *Theorie der sozialen Marktwirtschaft*—theory of the social market economy). Some readers may be surprised that this branch, which is perhaps the best-known speciality in German postwar economics, has not been mentioned earlier and in a more prominent place. I shall account for this presently.

German neoliberalism has its roots in the *Freiburger Schule*, a group of liberal economists in the University of Freiburg who started to discuss the problem of *modernizing* liberalism a quarter of a century ago. The nucleus of this group soon became Walter Eucken (d. 1950), who developed his concept of a new liberal order in various writings in the last ten years of his life.<sup>26</sup> Typical of his thought was the belief in a fairly rigid relationship between the different market forms and a corresponding social and political setting. The choice of a *proper* market order becomes, therefore, the crucial problem for mankind. Eucken, who believed that this choice can be made comparatively freely (irrespective of the historical, technical, and economic stage of society and the relative strength of different classes), developed—in the words of one of his followers—"a simple, complete, understandable and crystal-clear pattern of possibilities for the shaping and regulation (*Gestaltungs- und Ordnungsmöglichkeiten*) of the economic system."<sup>27</sup> The pattern which the Eucken circle (the neoliberals or ORDO-liberals) has chosen—for economic, political, ideological, and philosophical reasons—is a revised liberalism. Gone is the belief in the automatic working of *laissez-faire*, but a hostility against monopolies and state intervention has remained. The economic concept of the neoliberals envisages a minimum of state action necessary to preserve free markets, competition, and small business, and to prevent the social excesses of pure *laissez-faire*.

Whether the reader is enchanted by this program or whether he rejects it, he will understand why so little room has been spared for neoliberalism in this essay on the main trends in current German economic

*theory*. A detailed study of neoliberalism belongs in the field of German ideologies. It would then be seen that before 1945 some of the neoliberal writings represented a courageous independence vis-à-vis the basic fascist economic tenets, but that more recently they have turned mainly into a kind of apologetics for the present-day variety of Western German capitalism combined with a *petit-bourgeois* aversion against the advance of the big monopolies.

By saying that neoliberalism as a "school" offers more of interest to the chronicler of economic ideologies than to the student of economic theories, I do not want to suggest that members of this group have contributed nothing to the theoretical discussion. This is by no means true. If one goes through the pages of the ORDO yearbooks (an annual publication founded by the neoliberal group in 1948 as their main platform) one finds many interesting articles dealing with various aspects of economic theory. But in so far as they are of *general* theoretical interest they could have been written by other economists as well. It would be difficult to detect in them a special neoliberal stamp.<sup>28</sup>

The ORDO circle stands out because it is the only group of economists which continuously and massively presses for a certain (though vaguely defined) economic policy. But its presence has given a particular fillip to the discussion of problems of the "proper" economic order (*Wirtschaftsordnung*). The number of publications touching issues of this type is very large; they range from short essays to voluminous treatises. All sorts of views are represented, like the catholic standpoint of Oswald von Nell-Breuning<sup>29</sup> who takes his inspiration from the medieval ideas of an ordered hierarchy of the body politic and from the papal encyclicals or full employment ideologies of the current Anglo-Saxon type,<sup>30</sup> or again social-democratic and similar reformist proposals of a mildly interventionist character.<sup>31</sup>

<sup>28</sup> It may be significant that the specifically neoliberal themes in the ORDO yearbooks have declined in number as the years passed by. In the first volume (1948) eight out of the nine main contributions dealt quite clearly with neoliberal themes (economic order, monopoly, individualism, etc.). Of the twelve contributions in Vol. XI (1959) practically none could be termed as typically or exclusively neoliberal (the one exception perhaps being some critical notes on economic integration by Wilhelm Röpke).

<sup>29</sup> See, for instance, his *Wirtschaft und Gesellschaft, Band I: Grundfragen*, Freiburg 1956.

<sup>30</sup> For instance, E. Preiser, *Die Zukunft unserer Wirtschaftsordnung*, 2d ed. Göttingen 1955.

<sup>31</sup> Here we may mention K. Schiller, *Sozialismus und Wettbewerb*, Hamburg 1955, and the voluminous treatise by H. Bayer, *Wirtschaftsgestaltung*, Berlin 1958, which views the economic process as a multitude of tensions and looks for an economic order that would regulate and ease the tensions. The views of various writers on problems of economic order can be found in E. Lagler and J. Messner, eds., *Wirtschaftliche Entwicklung und soziale Ordnung*, Wien 1952.

### V. *Public Finance*

The theory of public finance and taxation has always occupied a rather special place in Central European economic science, far more so than in Anglo-Saxon literature. There it has usually been part of the general economic reasoning. Even Keynesianism and macroeconomic employment theory, which so enormously stimulated interest in fiscal action, did not lead to any clear separation of public finance theory from the main body of economic science. On the contrary, the new macroeconomic thinking and the interest in policy questions promoted a fuller integration of public finance problems into the basic theoretical framework.

On the continent, *Finanzwissenschaft* has a special standing of its own, almost on a par with the general subject of economics (*Volkswirtschaftslehre*). This tradition has its roots in the 17th and 18th centuries in the Cameralist writings which were greatly concerned with problems of public finance and taxation and had their main home in Italy, Germany, and Austria.<sup>82</sup> In the interwar years the neoclassical theory of public finance had a particularly strong basis in Italy. In fact, one of the best available English textbooks on the subject in those days was a translation from the Italian: Antonio de Viti de Marco's *First Principles of Public Finance*. But in German literature, too, public finance kept an important place. Since 1945, the interest in fiscal problems has been greatly stimulated by the Keynesian debates, and some of the most important contributions and liveliest debates have occurred in this field.

The main directions in which the diversified postwar literature on public finance has developed may be characterized by indicating the basic approach adopted in the works of three outstanding representatives of this branch of economics. Shortly after the war there appeared the fundamental treatise on income taxes by Fritz Neumark (then still an *émigré* at the University of Istanbul) [41]. He set a very high standard for the thorough investigation of all aspects of the subject concerned. There is no playing around with simplified models of the economy as a whole. The study has its roots firmly fixed in the essentials and the structure of the income tax itself. All possible characteristics and forms of an income tax are duly catalogued and discussed, and the door to reality is opened widely by giving extensive accounts of income-tax practice in seven countries. Its thorough and concrete approach and the wide sweep of its verbal analysis mark this work (and later contributions in a similar vein) as a continuation of the best classical tra-

ditions carried on at a higher level of specialization. Yet it would be a mistake to see only the traditional side of this work. In the chapters on shifting and on cyclical fluctuations, F. Neumark delves deeply into the problems introduced by the new economics. In this respect, his book carried very distinctly the stamp of the modern age and is clearly separated from some contemporary works which consist mainly of a high refinement of the prewar approach.<sup>33</sup> Yet it remains characteristic that these modern themes are modestly embedded in the descriptive and classificatory structure of the work.

At the opposite end of the spectrum stands Heinz Haller's *Finanzpolitik* [22]. Here the Anglo-Saxon reader well versed in Keynesian and post-Keynesian literature would feel at home right from the start. The basis of the book lies in its extensively developed macroeconomic models (illustrated by numerous diagrams) of income and employment with attention concentrated on the government sector. The models serve to tackle the main problems of the book: budgetary policies toward a stable income, and the shifting and incidence of taxation. In the course of these discussions, many of the newer theoretical problems connected with employment policy come up for close inspection. Thus Haller's treatment of the balanced-budget multiplier<sup>34</sup> represents an interesting investigation of the various secondary effects of a (balanced) budget increase showing that an expansionary effect will only occur under certain circumstances.

Macroeconomic relationships under the influence of a tax system are Haller's main interest. The various taxes with their special aspects and peculiarities are of lesser importance to him. They receive some attention but mainly in combination with the question of the overall efficiency of the tax system. Similarly, the institutional framework is only roughly incorporated in the premises of the models; only in the final chapter does it receive some detailed treatment. In general, Haller's approach is that of the "economic engineer" (familiar from many works in Anglo-Saxon literature) whose theoretical models serve to show the complex consequences of fiscal action, and thus, it is hoped, will aid and improve fiscal policy. *What* this fiscal policy is likely to be in actual practice is largely determined by factors outside the chosen boundaries.

It is here that the third approach appears, which finds its fullest expression in *Finanzpolitik* by Günter Schmolders [50]. Tax policy and fiscal action are traced back to their psychological, sociological, and

<sup>33</sup> See, for instance, W. Gerloff, *Öffentliche Finanzwirtschaft*, 2d ed. Frankfurt a.M. 1948, I, 1950, II; A. Amonn, *Grundsätze der Finanzwissenschaft*, Bern 1947.

institutional origins. It is not so much the question of what economic consequences will follow from a certain fiscal measure that occupies Schmölders' mind. This question is treated, but often in a rather vague manner.<sup>85</sup> The main trend of the analysis is directed toward a discovery of the pulls and stresses from which the aims for fiscal policy emanate and which delimit the space for fiscal action. While Haller wants to show how a desired aim can be achieved or what consequences will flow from a certain action, Schmölders wants to find out what will be desired and what is practically possible in a given institutional setup. This is an important and legitimate theoretical question. In the hands of Schmölders, it suffers from insufficient insight into the driving forces of capitalist society. Thus, in spite of many interesting details and important additions to our knowledge, Schmölders' work does not reach that depth of understanding to which his kind of approach should ultimately lead.

Neumark, Haller, and Schmölders were chosen as significant representatives of the different types of economic thinking in the field of public finance. With regard to both content and persons, the discussion naturally ranges over a far wider field. A good idea of the variety of research can be gained by looking at the new (second) edition of the three-volume encyclopedia of public finance [63] or at the issues of the *Finanzarchiv*, an economic journal especially dedicated to problems of public finance.

It was in the pages of this journal that one of the liveliest theoretical debates of the postwar period took place. Prominent German-speaking economists on both sides of the Atlantic engaged in the discussion which extended over two years: Carl Föhl, Hans Peter, Hans-Joachim Rüstow, Rudolf Stucken, Werner Ehrlicher, Gerhard Colm, Hans Neisser, Wilhelm Krelle, Heinz Haller, Karl Häuser, Rudolf Richter, and Horst C. Recktenwald. It was opened by a pointed and provocatively formulated article by Föhl [16, 88 ff.], in which he argued that any hope of improving the income distribution with the aid of a progressive profit tax must be disappointing. A profit tax would be completely shifted to nonentrepreneurs; gross profits would rise to such an extent as to leave net profits unimpaired. This conclusion was derived on the basis of an instantaneous (i.e., lagless) circular flow model of the sort which Föhl had previously introduced in his major work on macroeconomics.<sup>86</sup>

Reduced to its barest essentials his argument runs as follows. Starting with a fully employed economy and assuming that production remains at that level, we can divide the income flow into (contractual)

<sup>85</sup> A relevant section is significantly subtitled: "In the maze of tax consequences."

<sup>86</sup> See footnote 11, p. 9.

factor incomes and entrepreneurial incomes. Neglecting for the moment factor savings, the factor incomes in an uninterrupted flow model will equal factor consumption, and the entrepreneurial incomes (profits) will equal investment and entrepreneurial consumption. Next we assume that a tax on profits is introduced and that the proceeds of these taxes are immediately spent on goods and services or passed on to government employees, old-age pensioners, and others, who in turn buy consumption goods. The money taxed away from the entrepreneurs would, therefore, return to them in the form of an additional demand of nonentrepreneurs for consumption goods. The entrepreneurs would, under these circumstances, maintain their consumption and investment expenditure. Total demand and gross profits would rise by exactly the amount of the profit tax. Since production is unchanged, prices would go up and this would curtail the consumption of the factors to an extent that is needed to free the resources required by the state. The tax has been completely shifted. The argument is not altered when we allow for factor savings, as long as the savings remain unchanged after the imposition of the tax.

Brought down to a still more simplified level we can visualize the Föhl model as an economy of consuming factors and investing entrepreneurs. The state wants to raise funds for consumption purposes. With total product and investment given, the burden of the state expenditure must ultimately fall on the consuming factors, no matter where the taxes are initially placed.

It is perhaps not surprising that the article with its sharp formulations drew forth a whole chorus of critical replies. Many of the critics shared Föhl's skepticism about the effectiveness of progressive taxation for redistributive policies, but all of them attacked his complete negation of any effect whatever.

The first replies turned against isolated shortcomings in Föhl's method or premises. Rüstow [47, 360 ff.] replaced Föhl's instantaneous flow model by a lagged approach which—if undisturbed—would in the end yield the same result as Föhl's analysis. (The parallel to the instantaneous and lagged multiplier is evident.) But *during* the period of expansion various adjustments may retard the process. The profit tax will influence the investment and consumption decisions of employers, and the rising price level will lead to counteractions by the central bank and the government. The final result will, therefore, differ somewhat from Föhl's solution. In particular, a redistribution of incomes among *entrepreneurs* is to be expected. Stucken and Ehrlicher [58, 367 ff.] stress the fact that the taxed profits will not immediately enter the market. Even if the state spends the proceeds without delay, the beneficiaries (pensioners, government employees, etc.) will spread

their consumption over a period. With a given quantity of money (and unchanged velocity of circulation in the rest of the economy), the increase in prices and turnover which would fully restore the pretax profits will not materialize. Investment of capitalist consumption will be reduced unless an adequate credit expansion—tacitly included in Föhl's model—opens the door for the required price increases. Further factors mentioned by the two authors are: changes in stocks leading to (involuntary) changes in investment, complications stemming from the uneven distribution of the changed expenditure structure, and the attempt of wage earners to maintain their real wages and the consequent necessity of the monetary authorities to intervene in the resulting price-wage spiral. Several modifications to the Föhl argument are proposed by Colm [13, 525 ff.] who regards the analysis as too general and built too much on premises derived from the situation in postwar Germany. Among his more important points are the assertion that in an underdeveloped or growing economy a profit tax may help to bring the (individual and corporate) saving intentions into line with changing investment decisions; a criticism of the division of income earners into an investing upper class and a consuming lower class as being too simplified; a reminder that progressive taxation introduced in war and emergency periods was designed to eat into investment as well as into consumption expenditures. Finally he points out that accepted standards of fairness and equity will limit the administrative feasibility of tax reforms.

The next group of participants in the debate went right down to a dissection of Föhl's model and analytical method, in order to find out where the "trouble" originates. Neisser [40, 687 ff.] lays particular stress on structural shifts in production from investment to consumption. These follow after the imposition of the profit tax which reduces the immediate demand for investment goods while the profitability of the consumption goods industries grows with the consumption expenditure of the additionally employed government staff. Föhl's model is charged with being too rigidly divided into two productive compartments (consumption and investment) and for not paying sufficient attention to secondary behavioral reactions. A thorough dissection of the Föhl model is contributed by Krelle [33, 22 ff.] who shows that Föhl's results—the full and unavoidable shifting of a profit tax—follow quite necessarily from his *assumption* (hidden away in his flow diagrams and matrices) of unchanged investment and capitalist consumption. But this is only one of several possible cases. The practical outcome will depend on price and investment reactions after the tax change. The reaction functions must be obtained from factual observation and this is lacking in Föhl's study. Krelle contributes a mathematical model

lished in advance of the 1960 Congress which dealt with concentration tendencies in the modern economy [3].

Among the theoretical fields which obtained a fruitful stimulus from the activities of the *Verein für Socialpolitik* the problem of income distribution stands out with particular force. This was the subject of the 1956 Congress [26] and of special working parties [51]. In this series some interesting and important contributions have appeared, like Hans Peter's thoughtful essay on the limitations of purely economic distribution theories; Wilhelm Krelle's attempt at a macroeconomic distribution theory;<sup>39</sup> Jürg Niehans' extensive formal analysis of the influence of wage changes, technical progress, taxation, and saving on prices, production, and income distribution; and Gottfried Bombach's comparison of the basic determinants in different distribution theories.<sup>40</sup>

There are other professional societies in Germany, Austria, and Switzerland but none of them plays a role comparable to that of the *Verein für Socialpolitik*. Reference should be made, however, to the *List-Gesellschaft* (like the *Verein für Socialpolitik* recreated after the war) because it has acted and still acts as a stimulus to the investigation of problems connected with economic integration. Under its auspices appeared the only thorough *theoretically* oriented study on economic integration [49] (there are any number of publications dealing with *applied* aspects of integration). The study builds an impressive structure on the theoretical elements provided by J. Meade, J. Viner, and J. Tinbergen. It is indeed surprising that the *theory* of customs unions has been mainly developed in the United States and Britain, while the practical steps were taken on the continent.<sup>41</sup>

<sup>39</sup> Starting from the identity  $B/Y = B/K \cdot K/Y$ , where  $B$  stands for property income,  $Y$  for national income and  $K$  for the private capital stock, the share of property income in total income is seen as the product of the "real" rate of interest ( $B/K$ ) and the capital-output ratio. Krelle then proceeds to discover some of the cyclical and long-run tendencies of these two components.

A macroeconomic distribution theory on lines similar to Kaldor's "Keynesian" theory ("Alternative Theories of Distribution," *Rev. Econ. Stud.*, 1955-56, 23, has been published by E. Schneider in *L'Industria* (No. 2/1957); "Einkommen und Einkommensverteilung in der makroökonomischen Theorie" (English translation "Income and Income Distribution in Macro-economic Theory" in *International Economic Papers*, No. 8, 1958). Preiser's contributions to distribution theory have been mentioned in a different context (see above, p. 13).

<sup>40</sup> The article by Peter and Krelle are contained (besides others) in W. G. Hoffmann, ed., *op. cit.*, 42 ff. and 55 ff.; the articles by Niehans and Bombach in E. Schneider, ed., *Einkommensverteilung und technischer Fortschritt*, 9 ff. and 95 ff.

<sup>41</sup> Not that international trade problems have been altogether neglected in German economics, but there is no special theoretical treatment of the problems connected with integration. In the general field of international economics we find useful textbooks like A. Predöhl's theoretical and historical *Aussenwirtschaft. Weltwirtschaft, Handelspolitik und Währungspolitik*, Göttingen 1949, or E. Küng's monumental work on the balance of payments (*Zahlungsbilanspolitik*, Zürich-Tübingen 1959)—with its 900 pages of truly Ameri-

Institutes of economic research have particularly flowered in Germany. Their origin goes back to the twenties when the first were founded in Berlin and Vienna as institutes for cyclical research to study the *Konjunkturlage* (cyclical situation). Since then they have greatly expanded both in personnel and in the fields covered by their research. They differ from the National Bureau of Economic Research in New York and the National Institute of Economic and Social Research in London in their greater concentration on comparatively short-term and topical research projects.<sup>43</sup> They must also be distinguished from university institutes (which exist in large numbers), since they are independent of the universities and work with a staff of their own. There are four big institutes of this sort in Germany (Berlin, München, Essen, Kiel) and one in Austria (Vienna). In Switzerland, they are attached to universities, one to the Technical University (*Eidgenössische Technische Hochschule*) in Zürich, and one—specializing on foreign trade problems—to the Commercial University (*Handels-Hochschule*) in St. Gallen.

The existence of these special institutes has meant that much of the applied research which in Anglo-Saxon countries comes out of the universities and appears in the ordinary journals is, in the German-speaking countries, to be found in the publications of the research institutes. A considerable amount of valuable material has appeared in this way. The IFO-Institute in Munich has developed the *Konjunkturtest* [38], a method of obtaining quickly (with the aid of questionnaires sent out to firms) nonquantitative short-term indicators of the direction of economic changes, and has experimented in various ways to squeeze quantitative estimates and other information out of the rough-and-ready answers supplied by business [2, 159 ff.]. It was in the publications of the Berlin Institute where Albert Wissler (d. 1957) ran his cute commentary on the economic situation and where Ferdinand Grunig<sup>43</sup> developed *quarterly* national income accounts (the first in Europe). Here we find also the important pioneer work by Rolf Kren-

can textbook dimensions. Among original contributions to detailed aspects of international trade theory the articles by Herbert Giersch deserve particular notice. See his "Akzelerationsprinzip und Importneigung," *Weltwirtschaftliches Archiv*, 1953 I, 70, 241 ff., and "Das Handelsoptimum," *Weltwirtschaftliches Archiv*, 1956 I, 76, 1 ff. The articles have been translated into English: "The Acceleration Principle and the Propensity of Import" appeared in *International Economic Papers* No. 4 (1954), "The Trade Optimum" in *International Economic Papers* No. 7 (1957).

<sup>43</sup> With the publication of its *National Institute Economic Review* since January 1959, the London Institute has entered the sphere of activities typical for the German and Austrian institutes.

<sup>44</sup> See above, p. 9.

gel on capital growth, capital-output ratios, etc.<sup>44</sup> The work carried on in the Institute in Vienna has done a great deal to lay bare the mechanism of the economic process and to explain the macroeconomic quantitative interrelationships in the Austrian economy.<sup>45</sup> The various new tendencies in European and world trade are regularly analyzed by the Institutes in Kiel and St. Gallen.<sup>46</sup>

These few indications of the work done by the institutes were only given by way of example. They should suffice to give an idea of the part the institutes play in the research activity of the German-speaking countries. More recently the amount of quantitative research carried out within the universities has grown considerably.<sup>47</sup> This is a healthy sign that an unwelcome tradition of the past—a certain disdain to empirical research in academic circles—is rapidly breaking down. Of course, with the turn toward more realistic research a host of new problems arises: availability and reliability of data, relevance of the models chosen, questions of testing, and the like. But it would be unwarranted to go into these sorrows in this article. They represent by no means a special German headache. It is shared by economists all over the world.

### VII. *Concluding Remarks*

The preceding pages, in spite of their incompleteness, have shown—so it is hoped—that over the past fifteen years German economics has moved to a considerable extent toward current Anglo-Saxon trends without losing some distinctive marks of its own. Similar tendencies will probably be recognizable in other “national” theories. How could it be otherwise in a world where language barriers are rapidly breaking down with the increasing knowledge of English and with the growing number of translations; and where personal contacts are facilitated (and sometimes over-facilitated) by the rising number of congresses visited and miles traveled?

Krelle, *Volkswirtschaftliche Gesamtrechnung einschliesslich input-output Analyse mit Zahlen für die Bundesrepublik Deutschland*, Berlin 1959.

How will it go on? The supreme test for an economic theorist is to try his hand at forecasting future trends. Is the expositor of current economic doctrines obliged to subject himself to a similar test? I doubt it. However, the query about further developments remains a legitimate one and demands at least a tentative reply. The question is whether or not German economics is likely to move still further toward the trends which are visible in American and British economics and lose any special traits it possesses. We may question further whether or not such a development would be desirable.

Let us take the second question first. One could very well ask what point there can be in maintaining national or traditional differences in the approach to a common subject. After all, there can be only one "truth" and the quicker all theoretical approaches converge toward the "best" method, the better. This view could be accepted easily if the subject matter of economics were comparatively straightforward and uncomplicated. However, the very opposite is the case. Like most social sciences, economics throws up a multitude of questions, each of which has a large number of different and changing aspects. The choice of relevant questions and aspects is by no means clearly dictated by the subject itself. The choice will be influenced by the economic and political situation, by the predilections and ideology of the theorist, and by the analytical methods and traditions with which he has been nurtured. Different choices will lead to different approaches, each of which may spotlight a different aspect of a complex problem. Therefore, a certain degree of variation in methods, traditions, and starting points may be an asset rather than a disadvantage.

Between these different approaches, competition and cooperation can and does exist *within* each country and does not necessarily require national or language barriers to survive. The fact remains, however, that within a given country, with common language, traditions, educational institutions, and so on, one or a few "schools" will usually sweep the scene at the cost of others. If we remember that economics is not free from swings of fashion (in the choice of subjects and methods) the danger of too much uniformity is obvious. Seen from this angle, the preservation of some differences in the approach to economics in the international sphere is perhaps not quite undesirable. To be really fruitful, such differentiation must be supplemented by constant mutual contact and a lively exchange of notes. In this respect, much remains to be done. Until now the stream of information has been moving rather unevenly: fairly quickly from Anglo-Saxon sources to the rest of the world, but only hesitatingly and slowly in the other direction.<sup>48</sup>

<sup>48</sup> A valuable contribution in this field is made by *International Economic Papers*, the journal of translations published by the International Economic Association.

It would be a good thing if this stream of information could be widened and the "balance of information" improved.

Having decided that some national or traditional differentiation in approach may be an advantage, let us return to the first question. Is it likely that German, Swiss, and Austrian economics will continue to follow a slightly different path from that of Anglo-Saxon economics? There can be little doubt that a number of trends will become very similar. This tendency will be the natural consequence of growing specialization in economics. It will necessitate closer contacts and a common language with colleagues across the frontier—with whom, however, communication will be much easier than with fellow-economists from a different branch in one's own country. Apart from this internationalization of highly specialized branches of economic theory, we can expect some special characteristics to continue, at least for some time to come.

The traditional nexus between economics, law, and politics in a single faculty still exists in many universities in Western Germany, Austria, and Switzerland, or has only recently been loosened. This means that "literary" economics will continue to play a more important role than in the United States; the "mathematization" of the theoretical language will be slower and less universal. Not only will the method of analysis be influenced but also the aspects which are analyzed. The contact with law subjects promotes a consideration of institutional and historical influences.<sup>49</sup> Econometrics, with its stress on quantitative and purely economic factors—though also advancing, is less likely to conquer the scene to the extent it has in the Anglo-Saxon countries.

A similar effect emanates from the secondary school system which is still based on the ideal of general education and does not permit much specialization at the pre-university level. Therefore, the student, even if inclined toward mathematics and the exact sciences, has at least a nodding acquaintance with the humanities. This knowledge will leave its imprint on the work of the economics student—at least sometimes. Psychology, philosophy, "cultural background," and their influence on *homo oeconomicus* will come more quickly to his mind than to the mind of the more specialized college boy. All this will be strengthened by the perseverance of past traditions. In addition, in Austria and in Switzerland (as in other small nations) the smallness of the country acts as a brake on too extensive specialization and may promote a greater awareness of the interdependencies of the specialized branches of economic theory—provided their output can still be comprehended by the non-specialist.

<sup>49</sup> This provides affinities to the American institutionalists. Their survival is, however, probably less secure than that of their German counterparts.

At its best, therefore, German economics may be able to contribute a comparatively large proportion of economic literature that avoids the dangers of over-specialization and extreme mathematical sophistication. At its worst, this line of approach may mean that what is gained in breadth and generality is being lost in accuracy and reliability.

These tentative prognostications must be understood as broad generalizations pointing toward *relative weights* in the large body of research taking place in the Anglo-Saxon and German-speaking countries. For each type of theoretical study in one region it should not be difficult to find a spiritually and methodologically related work in the other area. However, when we compare the theoretical outputs as a whole, we should expect that their structure will not completely match for a considerable time to come.

Contrary to several other small European countries, such as Sweden and Austria, the Netherlands cannot claim to have a great tradition in economic theory which goes back during many decades. Originally, economics was a minor field that could be studied in the departments of law of the universities; the first change in this respect took place in 1913 when the Netherlands School of Economics was established at Rotterdam. In the next decade this move was followed in two other places, leading to the Department of Economics of the (Municipal) University of Amsterdam and the Catholic School of Economics at Tilburg. After the second World War two other universities established

economics departments, the State University of Groningen and the Free (Calvinist) University of Amsterdam.

The structure of these institutions differs from that of their American counterparts in several respects. For one thing, as in many other continental countries, economic theory and business administration have a nearly symmetric position in the teaching system, and it is only in the last ten years or so that graduate students have been permitted to specialize in either of these fields. For another, only a small minority of the graduate students have a university career in mind, so that the number of Ph.D. theses is also small compared with the total number of graduates. The situation is changing now due to the increasing size of university staffs and hence the better possibilities for a university career, but as a whole this development is still in the infant stage.

The situation just described is, of course, no stimulus for large-scale research activities. We must add to this the language barrier. Until the mid-thirties the *Germania docet* still did its work, a considerable part of the reading lists consisting of German textbooks. This situation changed gradually under Keynesian and political influences, then there was the interruption of the war, but at the moment the Anglo-Saxon influence is clearly dominating. This is well illustrated by the fact that J. G. Koopmans' 1933 essay [20] on neutral money was published in German, whereas later monetary discussions by Holtrop, Tinbergen, and Witteveen were summarized by H. C. Bos [11] in English. I should also mention J. Pen's Ph.D. thesis (in Dutch) on collective bargaining [31], followed by his article in English [30] on the same subject.

There is an important exception to the over-all picture, which is largely due to the work of one man—J. Tinbergen. In the 1930's he became head of a division of the Central Bureau of Statistics, where he and his collaborators carried out a large number of studies in econometrics, including the first econometric model that was ever constructed for the Netherlands as a whole. This work was continued after the war, partly in the Central Bureau of Statistics but mainly in the Central Planning Bureau of which Tinbergen was the director from 1945 until 1955; after 1956 a new stream of econometric investigations came from the Econometric Institute of the Netherlands School of Economics. A rather large proportion of the research in economics in the Netherlands as a whole has, therefore, a mathematical character. Another interesting feature is that a relatively sizable proportion of the research is carried out by workers who cooperate in an institute or a bureau and who continue to be staff members of such institutions during a relatively long period of time. The mobility of labor is much less than in the United States, partly no doubt because the country is so small.

In this article, an attempt is made to survey four more or less related research activities. They are all mathematical to some degree, which means that the picture is somewhat one-sided; but the choice has the advantage of coherence. Section I. deals with the empirical side of model building; Section II. with some methodological aspects; Section III. with some studies in demand analysis; Section IV. with the use of models for decision purposes.

### I. *Empirical Results in Model Building: The Example of Import Demand*

The Central Planning Bureau's econometric model serves the dual purpose of providing forecasts for next year's values of endogenous variables, given certain assumptions on the exogenous variables, and of estimating the effects of alternative measures of government economic policy. Actually, it is not entirely correct to speak about "the" model, because the procedure followed amounted to changing its structure in the light of evidence and changing theoretical convictions. The first of this series of models was constructed in the early fifties, its main ingredients being intuition, courage, and least squares. Sophistication came later. At the moment a research project is under way to make a better model. Some of the earlier results have been reported by P. J. Verdoorn and C. J. Van Eijk at the Bilbao Meeting of the Econometric Society [49].

Although the general flavor of these models is not different from that of similar models constructed by L. R. Klein for the United States, there are special features which are due to the fact that the Netherlands is a small country and, consequently, foreign trade is of great relative importance. Hence imports and exports deserve careful attention; the same is true for wages and prices, for the relative price level compared with that of competitors abroad is one of the determinants of the components of foreign trade. It may, therefore, be of interest to pay some attention to the import demand equation as it was estimated recently by Verdoorn.<sup>1</sup>

Let us write  $m$  for the annual percentage change in the volume of imports of goods (services being excluded). Then the equation runs as follows:

$$\begin{aligned}
 (1) \quad m = & 1.24v_m + 0.29\Delta v_m + 2.50J - 0.38p_1 + 0.32\Delta p_2 \\
 & (0.25) \quad (0.15) \qquad (0.14) \quad (0.09) \\
 & - 0.30k + 0.11k'. \\
 & (0.09) \quad (0.07)
 \end{aligned}$$

<sup>1</sup> The account which follows is largely derived from a syllabus by T. Klock [18].

Its structure can be explained conveniently under the following four headings:

1. The first two terms deal with total output (excluding invisibles and inventory changes),  $v_m$  being the percentage change in this variable. It is obtained by weighting the four components of total output by their import contents:

$$(2) \quad v_m = 0.45c + 0.15x + 0.11i + 0.29b,$$

where  $c$  stands for the percentage change in total private consumption,  $x$  for that in autonomous expenditure (government expenditure on commodities, investment by government enterprises, and residential construction),  $i$  for that in gross private investment (excluding residential construction and inventory changes), and  $b$  for the percentage change in the volume of exports of commodities. It is interesting to compare the weights of (2) with those of the corresponding definitional equation. To see how this works out we consider the Keynesian identity  $Y = C + I$ , where the three variables stand successively for income, consumption, and investment. Now the variables in (2) are all annual percentage changes, so we should write the Keynesian identity in the form

$$(3) \quad 100 \frac{\Delta Y}{Y_{-1}} = \frac{C_{-1}}{Y_{-1}} \left( 100 \frac{\Delta C}{C_{-1}} \right) + \frac{I_{-1}}{Y_{-1}} \left( 100 \frac{\Delta I}{I_{-1}} \right),$$

whence it follows that the coefficients of the identity in this form are the lagged values of the ratios  $C/Y$  and  $I/Y$ . Obviously, these ratios are no constants; but as a first approximation they can be replaced by corresponding averages in the sample period. In our case this leads to the aggregate

$$(4) \quad v = 0.59c + 0.11x + 0.08i + 0.22b.$$

On comparing (2) with (4) we can conclude that the imports in the consumption sector are relatively less important than those in the other three sectors.

If we apply a linear approximation over time, we can write the first two terms on the right of (1) as

$$(5) \quad 1.24v_m + 0.29\{v_m - (v_m)_{-1}\} \sim 1.82(v_m)_{1/4},$$

which shows that these terms can be regarded as measuring the influences of output changes on imports with a lead of three months. This reflects the fact that imports are necessary before output is there. Given that the relation is linear in relative changes, we should interpret the coefficients as elasticities. In the present case the value is 1.82, i.e., well above 1, which implies that imports are rather sharply sensitive to relative changes in total output.

2. In the expenditure categories considered above, we excluded inven-

tory changes. The third term,  $2.50J$ , serves to correct for this omission. Since equation (1) is in relative changes,  $J$  itself should be defined in terms of relative changes in inventory changes. The precise definition is as follows:  $J$  is the first difference of the value of inventory changes expressed as a percentage of the value of last year's total output. (In accordance with  $v_m$  of (2), total output is defined as excluding invisibles and inventory changes.) It appears to be difficult to estimate the influence of  $J$ ; the elasticity value  $2\frac{1}{2}$  has the character of an a priori estimate.

3. The fourth and fifth terms of (1) deal with price effects. The definition of  $p_1$  is

$$(6) \quad p_1 = p_m - (p_2)_{-1} + 0.06\tau_{-1/2},$$

where  $p_m$  stands for the percentage change in the price level of imported commodities,  $p_2$  for that in the price index of total output (invisibles and inventory changes being again excluded), and  $\tau$  for the percentage change in the rate of indirect taxes less subsidies. Thus, the fourth term in (1),  $-0.38p_1$ , essentially says that if the import price level increases by 1 per cent relative to the home price level, the percentage change in the volume of imported commodities is about 0.4 below the value that would have been realized if import and home prices had moved proportionally. The half-year lag of  $p_2$  in (6) reflects the fact that, on average, import contracts are made about half a year before the goods are actually imported. The variable  $\tau$ , dealing with indirect taxes, serves as an approximation to import duties, the coefficient 0.06 being the weight used for this approximation; the four-month lag has the same meaning as the half-year lag of  $p_2$ . The fifth term ( $0.32\Delta p_2$ ), finally, serves to stress that sharpened inflationary strains at home encourage buying abroad.

4. The sixth and seventh terms of (1) have to do with quantitative import restrictions. These were introduced before the war and  $-0.30k$  represents their effect,  $k$  being the percentage of commodities (weighted according to their import shares in 1929) which were subject to such restrictions. After the war imports were liberalized and  $0.11k'$  stands for this effect,  $k'$  being the percentage of commodities (weighted according to their import shares in 1948) which were subject to liberalization.

The model as a whole contains 11 behavioral and technical equations as well as a large number of definitional equations. It has been estimated by the two-stage least-squares method (see Section on *Two-Stage Least-Squares*, p. 40 below) using data of the period 1923-38, 1949-57. Other behavioral and technical equations include a consumption function, an investment function, an equation explaining inventory changes, a demand-for-labor equation, an unemployment equation,

an export equation, and four equations describing different price indices.<sup>2</sup>

## II. *Econometric Methodology: Equation System Estimation*

The practical use of such models led naturally to an increased interest in the statistical methodology which underlies the construction of these models. Much of the basic work in this field had been done at the Cowles Commission for Research in Economics at the University of Chicago [14, 21], but the methods proposed were relatively complicated. Several successful efforts have been made to find simpler methods, at first in the Central Planning Bureau, later in the Econometric Institute. They will be illustrated here by means of a simple supply and demand system:

$$(7) \quad \begin{aligned} q(t) &= \alpha_1 p(t) + \alpha_2 k(t) + u_1(t) && \text{(supply)} \\ q(t) &= \alpha'_1 p(t) + \alpha'_2 \mu_1(t) + \alpha'_3 \mu_2(t) + u_2(t) && \text{(demand)} \end{aligned}$$

where  $q$  stands for the quantity bought and sold,  $p$  for the price,  $k$  for the price of a raw material,  $\mu_1$  and  $\mu_2$  for the incomes of two groups of buyers, and  $u_1$  and  $u_2$  for disturbance terms. The  $t$  in brackets stands for time (in years, say); it is supposed to take the values  $1, 2, \dots, T$ , where  $T$  is the number of observations (the sample size). The problem is to estimate the unknown parameters (the  $\alpha$ 's) on the basis of this sample of observations on the variables  $p, q, k, \mu_1$  and  $\mu_2$ . Constant terms have been deleted from (7); they are handled easily by measuring all variables as deviates from their means.

The usual approach is to take  $k, \mu_1$  and  $\mu_2$  as exogenous variables (whose values are nonstochastic) and  $p$  and  $q$  as endogenous variables (whose values are stochastic and correlated with the disturbances). The system (7) is then completely specified as soon as we specify the probabilistic properties of the disturbances. We shall specify that they have zero mean:

$$(8) \quad Eu_1(t) = Eu_2(t) = 0 \text{ for all } t,$$

that they are uncorrelated over time, and that they have constant variances and "contemporaneous" covariances:

$$(9) \quad E\{u_i(t)u_i(t')\} = \begin{cases} \sigma_i^2 & \text{if } t = t' \\ 0 & \text{if } t \neq t' \end{cases} \quad i = 1, 2;$$

$$(10) \quad E\{u_1(t)u_2(t')\} = \begin{cases} \rho\sigma_1\sigma_2 & \text{if } t = t' \\ 0 & \text{if } t \neq t', \end{cases}$$

<sup>2</sup> For more details, see the syllabus by Klok [18]. A very concise treatment is also given in the Appendix of [12].

where  $\sigma_i$  is the standard deviation of  $u_i(t)$  and  $\rho$  is the coefficient of correlation of  $u_1(t)$  and  $u_2(t)$ .

### *Two-Stage Least-Squares*

Suppose now that we decide to estimate the supply equation by ordinary least-squares. These estimates are obtained by solving the following normal equations:

$$(11) \quad \begin{bmatrix} \Sigma pq \\ \Sigma kq \end{bmatrix} = \begin{bmatrix} \Sigma p^2 & \Sigma pk \\ \Sigma pk & \Sigma k^2 \end{bmatrix} \begin{bmatrix} (\hat{\alpha}_1)_{LS} \\ (\hat{\alpha}_2)_{LS} \end{bmatrix},$$

where the summations are all over  $t$  (from 1 till  $T$ ). The difficulty with respect to least-squares is that the estimator is biased and inconsistent, which is due to the fact that one of the explanatory variables ( $p$ ) is endogenous and hence correlated with the disturbance term. We can attack this problem in the following manner. The system (7) can be solved with respect to the endogenous values  $p(t)$  and  $q(t)$ , which leads to a new system of two equations (the reduced form of the original system), one for  $p(t)$  and one for  $q(t)$ . The former equation is

$$(12) \quad p(t) = \bar{p}(t) + \frac{u_2(t) - u_1(t)}{\alpha_1 - \alpha_1'},$$

where

$$(13) \quad \bar{p}(t) = \frac{-\alpha_2 k(t) + \alpha_2' \mu_1(t) + \alpha_1' \mu_2(t)}{\alpha_1 - \alpha_1'}.$$

Next, we write the supply equation in the following form:

$$(14) \quad q(t) = \alpha_1 \bar{p}(t) + \alpha_2 k(t) + \left\{ u_1(t) + \alpha_1 \frac{u_2(t) - u_1(t)}{\alpha_1 - \alpha_1'} \right\}$$

i.e., we replace  $p(t)$  by  $\bar{p}(t)$  in the right-hand side but add the error made by doing so to the disturbance term. Suppose finally that we decide to estimate  $\alpha_1$  by computing an ordinary least-squares regression of  $q$  on  $\bar{p}$  and  $k$ . In fact, it is not difficult to see that this would solve the problem of correlation between explanatory variables and disturbances. For  $\bar{p}(t)$  is a linear combination of the exogenous values  $k(t)$ ,  $\mu_1(t)$ ,  $\mu_2(t)$ , see (13), so that it is nonstochastic; hence, by replacing  $p$  by  $\bar{p}$  we avoid the problem of a regression on variables which are correlated with the disturbances.

However, there is now the new difficulty that we do not know  $\bar{p}(t)$ , because it depends on unknown parameters, see (13). As a first approximation we can estimate  $\bar{p}(t)$  by computing the reduced-form regression, i.e., by applying least-squares with  $p$  as dependent and  $k$ ,  $\mu_1$  and  $\mu_2$  as

independent variables. Let us write  $v(t)$  for the residuals of this regression, then  $p(t) - v(t)$  estimates  $\bar{p}(t)$ . Hence (14) is now approximated by

$$(15) \quad q(t) = \alpha_1\{p(t) - v(t)\} + \alpha_2 k(t) + \{u_1(t) + \alpha_1 v(t)\},$$

and we run a second regression (hence the name two-stage least-squares, 2SLS), where  $q$  is the dependent variable and  $p-v$  and  $k$  the independent variables. This leads to the following normal equations:

$$(16) \quad \begin{bmatrix} \Sigma(p-v)q \\ \Sigma kq \end{bmatrix} = \begin{bmatrix} \Sigma(p-v)^2 & \Sigma p k \\ \Sigma p k & \Sigma k^2 \end{bmatrix} \begin{bmatrix} a_1 \\ a_2 \end{bmatrix},$$

where  $a_1$  and  $a_2$  are the 2SLS-estimates of  $\alpha_1$  and  $\alpha_2$ , respectively. The matrix of sampling variances and covariances is  $\sigma_1^2$  (the common variance of the disturbances of the supply equation) times the inverse of the  $2 \times 2$  matrix on the right of (16):

$$(17) \quad V \begin{bmatrix} a_1 \\ a_2 \end{bmatrix} = \frac{\sigma_1^2}{\Sigma(p-v)^2 \Sigma k^2 - (\Sigma p k)^2} \begin{bmatrix} \Sigma k^2 & -\Sigma p k \\ -\Sigma p k & \Sigma(p-v)^2 \end{bmatrix},$$

apart from terms which can be neglected when the sample size is sufficiently large. The 2SLS-method was found by H. Theil [38, 41] and later and independently by R. Basman [3].

### Three-Stage Least-Squares

We shall now attack the same problem along slightly different lines. We start by observing that the ordinary least-squares approach (11) amounts to multiplying the supply equation by the explanatory values  $p(t)$  and  $k(t)$  and summing over  $t$ , so that two linear equations result from which the estimates can be solved; furthermore, that the difficulty with respect to least-squares was that in one case these multipliers [viz.,  $p(t)$ ] are endogenous rather than exogenous. But if this is the case, an obvious approach is to multiply the supply equation by the exogenous values  $k(t)$ ,  $\mu_1(t)$  and  $\mu_2(t)$ . Doing so, and summing over  $t$ , we obtain the following three equations:

$$(18) \quad \begin{aligned} \Sigma k q &= \alpha_1 \Sigma p k + \alpha_2 \Sigma k^2 + \Sigma k u_1 \\ \Sigma \mu_1 q &= \alpha_1 \Sigma p \mu_1 + \alpha_2 \Sigma k \mu_1 + \Sigma \mu_1 u_1 \\ \Sigma \mu_2 q &= \alpha_1 \Sigma p \mu_2 + \alpha_2 \Sigma k \mu_2 + \Sigma \mu_2 u_1. \end{aligned}$$

Let us do the same with the demand equation:

$$(19) \quad \begin{aligned} \Sigma k q &= \alpha'_1 \Sigma p k + \alpha'_2 \Sigma k \mu_1 + \alpha'_3 \Sigma k \mu_2 + \Sigma k u_2 \\ \Sigma \mu_1 q &= \alpha'_1 \Sigma p \mu_1 + \alpha'_2 \Sigma \mu_1^2 + \alpha'_3 \Sigma \mu_1 \mu_2 + \Sigma \mu_1 u_2 \\ \Sigma \mu_2 q &= \alpha'_1 \Sigma p \mu_2 + \alpha'_2 \Sigma \mu_1 \mu_2 + \alpha'_3 \Sigma \mu_2^2 + \Sigma \mu_2 u_2. \end{aligned}$$

It is not difficult to see that (18) and (19) can be combined as follows:

$$(20) \quad \begin{bmatrix} \Sigma kq \\ \Sigma \mu_1 q \\ \Sigma \mu_2 q \\ \Sigma kq \\ \Sigma \mu_1 q \\ \Sigma \mu_2 q \end{bmatrix} = \begin{bmatrix} \Sigma pk & \Sigma k^2 & 0 & 0 & 0 \\ \Sigma p\mu_1 & \Sigma k\mu_1 & 0 & 0 & 0 \\ \Sigma p\mu_2 & \Sigma k\mu_2 & 0 & 0 & 0 \\ 0 & 0 & \Sigma pk & \Sigma k\mu_1 & \Sigma k\mu_2 \\ 0 & 0 & \Sigma p\mu_1 & \Sigma \mu_1^2 & \Sigma \mu_1\mu_2 \\ 0 & 0 & \Sigma p\mu_2 & \Sigma \mu_1\mu_2 & \Sigma \mu_2^2 \end{bmatrix} \begin{bmatrix} \alpha_1 \\ \alpha_2 \\ \alpha_1' \\ \alpha_2' \\ \alpha_3' \end{bmatrix} + \begin{bmatrix} \Sigma ku_1 \\ \Sigma \mu_1 u_1 \\ \Sigma \mu_2 u_1 \\ \Sigma ku_2 \\ \Sigma \mu_1 u_2 \\ \Sigma \mu_2 u_2 \end{bmatrix},$$

which is a system of six equations in the five unknown coefficients (the  $\alpha$ 's) of the supply-and-demand system. This suggests that we are approaching a method by which all coefficients of the system are estimated simultaneously, rather than equation by equation as in 2SLS. Indeed, the three-stage least-squares method (3SLS), developed by A. Zellner and Theil [52], does precisely this. The main ideas can be described conveniently in the following three steps:

1. We regard the last vector on the right of (20) as a disturbance vector. One might think that there is a complication due to the fact that its elements (such as  $\Sigma ku_1$ ,  $\Sigma \mu_1 u_1$ ,  $\dots$ ) are correlated with  $\Sigma pk$ ,  $\Sigma p\mu_1$ ,  $\dots$  (the elements of the  $6 \times 5$  matrix in (20)); but it can be proved that these correlations are asymptotically zero and hence do not matter for large samples.

2. The most straightforward approach would seem to run an ordinary least-squares regression on (20), i.e., to regard the left-hand column as six values taken by the dependent variable and the right-hand  $6 \times 5$  matrix as the array of values taken by five independent variables. This would lead directly to estimates of the five  $\alpha$ 's. However, ordinary least-squares is efficient only if the disturbances have all the same variance and are all uncorrelated, which is not the case here. For example, the variance of the first disturbance is

$$(21) \quad \text{var} (\Sigma ku_1) = \sum_i \sum_{i'} k(i)k(i')E\{u_1(i)u_1(i')\} = \sigma_1^2 \Sigma k^2$$

and the variance of the fourth disturbance,  $\Sigma ku_2$ , is  $\sigma_2^2 \Sigma k^2$ , while their covariance is  $\rho\sigma_1\sigma_2 \Sigma k^2$ . In this way one can derive the complete  $6 \times 6$

covariance matrix of the disturbance vector. If this covariance matrix is known, one can apply A. C. Aitken's method of generalized least-squares [1] to estimate the  $\alpha$ 's from (20). This method essentially amounts to a linear transformation of the system (20) such that the six transformed disturbances have the same variance and are uncorrelated; thereafter one applies least-squares in the way described in the beginning of this paragraph.

3. A difficulty is that the covariance matrix of the disturbance vector is in general not known. We just found  $\sigma_1^2 \Sigma k^2$ ,  $\sigma_2^2 \Sigma k^2$ , and  $\rho \sigma_1 \sigma_2 \Sigma k^2$  for three elements of this matrix; and when continuing in this way we find that all these elements depend on  $\sigma_1$ ,  $\sigma_2$ , and/or  $\rho$ , which are in general as much unknown as the  $\alpha$ 's. However, it can be shown that if we replace  $\sigma_1$ ,  $\sigma_2$ , and  $\rho$  by their 2SLS-estimates, the asymptotic properties of the resulting 3SLS  $\alpha$ -estimates are not affected. Hence the procedure is as follows: first, determine the 2SLS-estimates of the  $\alpha$ 's, both of the supply and of the demand equation, and compute the implied estimated variances and covariance of the disturbances of these equations; second, estimate the  $6 \times 6$  covariance matrix of the disturbance vector in (20) on the basis of the latter estimates and apply generalized least-squares to find new estimates of all  $\alpha$ 's. These estimates are called those of three-stage least-squares, the generalized least-squares procedure being the origin of "three." It can be shown that 3SLS is in general asymptotically more efficient than 2SLS.

### *Linearized Maximum Likelihood*

An interesting question is obviously whether the estimates considered so far are as efficient as or less efficient than the maximum-likelihood methods which were introduced by the Cowles Commission. Answers are possible when the sample size is sufficiently large. Regarding 2SLS, this method is asymptotically as efficient as limited-information maximum likelihood. As to 3SLS, it was recently shown by T. Rothenberg and C. T. Leenders [33] that its estimator is asymptotically as efficient as full-information maximum likelihood, provided that there is no prior information on the variances and covariances of the disturbances of the equations.

Since 2SLS and 3SLS are computationally far simpler than their maximum-likelihood counterparts, the interesting problem which remains is how to estimate efficiently in case there is prior information on the covariance matrix of the disturbances. Of course, full-information maximum likelihood does estimate efficiently in that case, but the difficulty is that its estimates have to be solved from nonlinear estimation equations. This problem, too, was attacked successfully by Rothenberg and Leenders, who derived the method of linearized maximum likeli-

hood (LML) which is asymptotically as efficient as the full-information maximum likelihood method. The main idea can be described easily as follows. Let  $\phi$  be the logarithmic likelihood function and write  $\theta$  for the vector of all parameters of the system. Let  $f$  be the vector of first-order derivatives of  $\phi$ ; then  $f(t)=0$  is the set of equations from which the maximum-likelihood estimates (arranged in a vector  $t$ ) can be solved. The problem is that these equations are nonlinear. The LML method linearizes them, starting at the 2SLS-estimates (for which we write  $t_0$ ). This means that  $f(t)=0$  is replaced by

$$(22) \quad f(t_0) + F(t - t_0) = 0,$$

where  $F$  is the matrix of second-order derivatives of  $\phi$  evaluated at  $t_0$ . Of course, (22) is only an approximation to  $f(t)=0$ , but it can be shown that the approximation error does not affect the large-sample properties of the estimator. Since  $f(t_0)$  and  $F$  are known, the estimator  $t$  can be derived easily by premultiplying (22) by  $F^{-1}$ ; it can also be shown that minus this inverse matrix is the covariance matrix of the LML estimator, apart from terms which tend to vanish when the sample size is sufficiently large.

### *On Underidentified Equations and Undersized Samples*

There are situations in which the estimation methods discussed here break down. To see this we go back to the supply and demand system and suppose now that  $\alpha_2=0$ , i.e., the variable  $k$  is no longer one of the exogenous variables of the system. In that case the addition of the supply equation (possibly multiplied by any nonzero coefficient) to the demand equation yields another linear relation between  $q$ ,  $p$ ,  $\mu_1$  and  $\mu_2$  which cannot be distinguished from the demand equation on the basis of observations. This is the case of underidentification, which occurs as soon as the number of coefficients of an equation exceeds the number of exogenous variables in the system. When the two numbers are equal [as happens to be the case for the demand equation of (7)], we have the situation of just-identification for which the estimation methods can be simplified in certain respects.

But most econometric models are much larger than (7) in the sense that they consist of more equations. The number of exogenous variables is then usually considerably in excess of the number of coefficients to be estimated in the separate equations,<sup>8</sup> so that the identification problem ceases to be important. Another restriction then gains in importance: the number of exogenous variables should not exceed the number of observations. This must be so because we need the inverse of the moment matrix of these variables, which would be singular if there were

<sup>8</sup> When there are lagged variables (either endogenous or exogenous) these should be added to the set of (current) exogenous variables to form the set of all "predetermined" variables.

fewer observations than variables. But there are nevertheless situations, particularly for large models, where this restriction is violated. As T. Kloek and L. B. M. Mennes [19] argued, the best procedure is then to replace exogenous variables by a certain number of their principal components.

This problem of "undersized samples" stands in sharp contrast to the large-sample character of the theory which underlies the estimation methods. A. L. Nagar [25, 26, 27] made several efforts to improve on this aspect by evaluating the bias of certain simultaneous-equation estimators to the order  $1/T$  and their moment matrix to the order  $1/T^2$ ,  $T$  being the number of observations.

### III. *Studies in Demand Theory*

#### *The Leser-Somermeijer-Houthakker Model*

In the last few years Mr. W. H. Somermeijer of the Central Bureau of Statistics and his assistants carried out several analyses in demand theory. The model which they use is the same as that of C. E. V. Leser [23]; it was used independently by H. S. Houthakker in two recent publications [16, 17]. It can be considered conveniently in relation to statistical estimation theory as will become clear immediately.

Let  $w_i$  for  $i=1, \dots, n$  be the budget share of the  $i$ th commodity; then the model implies that

$$(23) \quad w_i = \frac{A_i(\mu, p_i)}{\sum A_j(\mu, p_j)}$$

with

$$(24) \quad A_i(\mu, p_i) = B_i(\mu/p_i)^{\alpha_i} u_i,$$

where  $\mu$  is income or total expenditure,  $p_i$  the price of the  $i$ th commodity,  $B_i$  and  $\alpha_i$  parameters to be estimated and  $u_i$  a disturbance. It is easily seen that the budget shares satisfy the condition that they be all nonnegative and add up to 1. It can also be shown that the form of the demand functions implied by (23)–(24) is such that the Slutsky equations and inequalities are satisfied provided that  $\alpha_i > -1$  for all  $i$ . The income elasticity of  $w_i$  is  $\alpha_i - \bar{\alpha}$  where  $\bar{\alpha} = \sum w_i \alpha_i$  is the weighted mean of all  $\alpha$ 's with the budget shares as weights. (In fact, it is quite instructive to formulate the demand theory (23)–(24) in terms of a discrete frequency distribution of which the  $\alpha_i$  are the  $n$  values and the  $w_i$  the corresponding relative frequencies.)

To estimate the parameters  $B_i$  and  $\alpha_i$  we have to get rid of the awkward denominator in (23). This can be done conveniently by taking the ratio  $w_i/w_j$ , the natural logarithm of which is

$$(25) \quad \log(w_i/w_j) = \log(B_i/B_j) + \alpha_i \log(\mu/p_i) - \alpha_j \log(\mu/p_j) + u_i - u_j.$$

We can formulate such relations for all possible pairs  $(i, j)$ , but these are obviously linearly dependent. Also, one has to take account of the fact that in general there exist nonzero correlations between the disturbances. For example, take  $i=1, j=2$  in (25), so that the disturbance becomes  $u_1(i) - u_2(i)$  in any period  $t$  (assuming that we deal with time series data)<sup>4</sup> Next, take  $i=1, j=3$  and hence  $u_1(i) - u_3(i)$ . Now if  $u_1(i)$ ,  $u_2(i)$  and  $u_3(i)$  are uncorrelated, the differences  $u_1(i) - u_2(i)$  and  $u_1(i) - u_3(i)$  are correlated and the covariance of these differences is the variance of  $u_1(i)$ . Therefore, as soon as one decides to estimate the  $\alpha$ 's by combining several relations (25) for different pairs  $(i, j)$ , one has to take account of the fact that, as in the case of three-stage least-squares (see above, page 42), there are correlations among the elements of the combined disturbance vector. This problem was attacked recently by Zellner [51] in a manner similar to the 3SLS method.

The analyses carried out by W. H. Somermeyer and his associates deal with consumption, both for time series and for cross-section data [35, 50], with the demand for imports and home production [34], and with the alternative uses of farm land depending on prices [36]. The statistical approach followed by them differs from the method outlined in the preceding paragraph.

### *Almost Additive Preferences*

Houthakker [17] argued that the demand functions implied by (23)–(24) can be considered as belonging to “additive preferences” in the following sense. Classical consumption theory is based on a utility function with the quantities  $q_1, \dots, q_n$  as arguments, which is maximized subject to the budget constraint  $\sum p_i q_i = \mu$ . This leads, under appropriate conditions, to unique demand functions which describe the  $q$ 's in terms of prices and income. By substituting these demand functions in the utility function, utility becomes a function of prices and income: it is the highest utility level attainable, given these prices and this income level. Now the demand functions (23)–(24) can be derived from such an “indirect” utility function with the following special property: it is the sum of  $n$  separate functions, each of which contains income and only one price.

This case of “separable” utilities is plausible enough when one has to do with goods which are characterized by little interdependence in the consumer's utility evaluation; but it is more plausible at the level of “direct” utility (depending on quantities, the  $q$ 's) than at the level of indirect utility. This was pursued further by Barten [2], who advanced the following theory of “almost additive preferences.” If utility is completely separable with respect to all  $n$  commodities (in the “di-

<sup>4</sup> When cross-section data are used,  $t$  stands for a household.

rect" sense), the  $n \times n$  matrix of second-order derivatives of the utility function,  $U$  say, is diagonal. When we accept the idea of decreasing marginal utilities, we can write  $U = -\bar{u}^2$  where  $\bar{u}$  is a diagonal matrix with positive elements on the diagonal. In the case of nonadditive preferences it is always possible to write  $U$  in the form  $-\bar{u}(I + \Theta)\bar{u}$ , where  $I$  is the  $n \times n$  unit matrix and  $\Theta$  a symmetric matrix with zeros on the diagonal. Thus  $\Theta$  can be regarded as measuring the degree of interdependence of the various goods in the consumer's utility scale. Now the inverse of  $U$  plays an important role in the demand functions. If the elements of  $\Theta$  are sufficiently close to zero, we can approximate as follows:

$$(26) \quad U^{-1} = -[\bar{u}(I + \Theta)\bar{u}]^{-1} \approx -\bar{u}^{-1}(I - \Theta)\bar{u}^{-1},$$

and preferences are regarded to be almost additive when (26) is considered to be a satisfactory approximation. It is easily seen from (26) that if the  $(i, j)$ th element of  $U$  vanishes, i.e., if the marginal utility of the  $i$ th commodity is independent of the  $j$ th consumption, the same element of  $U^{-1}$  vanishes too. This property is very convenient for the estimation of the price elasticities which will be considered now.

The utility function is maximized subject to the budget constraint in the conventional way, which implies the introduction of the Lagrangean multiplier  $\lambda$ , the marginal utility of income. This leads to the first-order equilibrium conditions, from which the demand functions can in principle be solved. By differentiating the first-order conditions with respect to income and prices, we obtain the following system of  $n+1$  equations:

$$(27) \quad \begin{bmatrix} U & p \\ p' & 0 \end{bmatrix} \begin{bmatrix} q_\mu & Q_p \\ -\lambda_\mu & -\lambda_p \end{bmatrix} = \begin{bmatrix} 0 & \lambda I \\ 1 & -q' \end{bmatrix},$$

where  $U$  is the matrix of second-order derivatives of the utility function which was discussed in the preceding paragraph,  $p$  is the column vector of prices,  $q_\mu$  the column vector of income derivatives of the demand function,  $Q_p$  the matrix of price derivatives, while  $\lambda_\mu$  and  $\lambda_p$  represent the derivatives of  $\lambda$  with respect to  $\mu$  and  $p$ , respectively. After some algebraic rearrangements we can express  $Q_p$  in terms of  $\lambda$ ,  $\lambda_\mu$ ,  $U$ ,  $q$  and  $q_\mu$ :

$$(28) \quad Q_p = \lambda U^{-1} - (\lambda/\lambda_\mu) q_\mu q'_\mu - q_\mu q'_p,$$

which expresses the price derivatives as the sum of three terms. The third is the income effect, the first two represent jointly the substitution effect. The off-diagonal elements of the first term represent the substitution effect insofar as this is due to the interaction of commodities in the consumer's utility evaluation; the second term deals with "overall"

substitution and expresses the fact that all commodities compete for the consumer's guilder.

Barten applied this theory to 14 commodity groups in the interwar and postwar period and permitted 11 elements of  $\Theta$  above the diagonal to differ from zero. He approximated his demand functions by a linear expression in the logarithms, so that the coefficients found are essentially elasticities. One difficulty in the estimation is that the coefficients are subject to nonlinear constraints; this follows directly from the second term on the right of (28), which contains products of income derivatives. Such nonlinear constraints have to be handled by an iterative procedure. Another difficulty is that a number of constraints deal with coefficients of different demand equations. This follows from the first term in the right-hand side of (28):  $\lambda U^{-1}$  is symmetric and hence the  $(i, j)$ th element, which occurs in the  $i$ th equation and describes part of the effect of the  $j$ th price, is equal to the  $(j, i)$ th element which has its place in the  $j$ th demand equation. It is, therefore, necessary to have two consecutive sets of computations, the first of which is on equation-by-equation basis and disregards constraints on coefficients of different equations, while the second takes such constraints into account by proceeding on equation system basis. Both sets are iterative (in view of the nonlinearity of certain constraints); the second set is essentially an application of Zellner's method as mentioned above, p. 45.

Barten added a third set of computations of a Bayesian nature to incorporate his prior beliefs on parameter values in a probabilistic manner. The approach will be illustrated here for the simple case of the demand for food (say):

$$(29) \quad \log F = \alpha + \beta_1 \log \mu + \beta_2 \log p + u,$$

where  $\beta_1$  is the income elasticity and  $\beta_2$  the price elasticity. Suppose now that we know (from previous experience, from introspection, or from any other source of information which is independent of the sample) that the income elasticity of food is likely to be between 0.4 and 0.6 and is very unlikely to lie outside the interval (0.3, 0.7). We can formalize such prior "uncertain" information approximately by saying that the income elasticity is subject to a prior distribution which is normal (say) with mean 0.5 and standard deviation 0.1. Thus, let  $r$  be the prior estimate of  $\beta_1$ , then

$$(30) \quad r = \beta_1 + v \quad \text{where} \quad Ev = 0, \quad Ev^2 = 0.01,$$

$v$  being the error of the prior estimate  $r$  which itself takes the value 0.5 in this case. The Bayesian procedure then implies that the sample information (29) and the prior information (30) are combined in the manner of Aitken's generalized least-squares. This is straightforward insofar as both kinds of information are linear in the parameters to be

estimated; there is a difficulty due to the fact that we need the ratio of the variance of  $u$  in (29) to the variance of  $v$  in (30), which is responsible for the fact that the theory is essentially of the large-sample variety. Reference is made to Theil and A. S. Goldberger [43] and Theil [42] and, for a slightly different set-up, to H. Raiffa and R. Schlaifer [32]. In Barten's case there are additional complications due to nonlinearities.

#### IV. *Models for Decision Purposes*

##### *Targets and Decision Rules*

The purpose of an econometric model may be confined to a better understanding of the working of the economy; it may also be to contribute to a more "rational" economic policy. Tinbergen was the first in the Netherlands who worked systematically in this area; a few years later other contributions were made by Theil. Since the relevant publications are all in English [41, 48], I shall confine myself to a brief outline.

Suppose we have a complete econometric model of which the reduced form exists. This reduced form describes the endogenous variables (e.g., consumption, investment, employment, and the like) in terms of lagged variables, exogenous variables, and random disturbances. None of the endogenous variables is controlled by the government, but some of the exogenous variables are, e.g., tax rates, government expenditure on goods and services, etc. Let us assume (to keep things simple) that all exogenous variables are government-controlled. Then the reduced form enables us to predict what will happen to the endogenous variables if these government variables are subject to given specified changes, i.e., if the government takes certain measures of economic policy. In this way the Central Planning Bureau is in a position to inform the government about the consequences of alternative lines of action. But the Tinbergenean approach turns things upside down. Tinbergen starts with given targets for the endogenous variables: a 5 per cent increase of employment in private industry, a constant price level of consumer goods, a  $\frac{1}{2}$  billion surplus on the balance of payments, etc. All these targets refer to next year, say. Suppose now that the number of such "target variables" is equal to the number of government-controlled variables. Then we can use the reduced form to compute the values which the latter variables should take in order that the former take their target values. In this way one uses the model to design a policy which leads to the desired targets.

It will be clear that this approach is subject to certain qualifications. For example, it is not always true that the number of target variables equals the number of government-controlled variables. If the former is larger there exists in general no solution; if it is smaller there are in gen-

eral infinitely many, so that it is then possible to take account of, say, preferences with respect to the values taken by controlled variables. A fundamental problem is that of uncertainty. It was mentioned at the beginning of the preceding paragraph that the reduced form contains random disturbances. It is only by neglecting such disturbances that we can arrive at unique values for the controlled variables in the decision problem; if we do wish to take account of random variation, there are no such values which lead to the targets with probability 1. A similar situation arises if the model contains exogenous variables which are not controlled, such as the import price level. The size of the population, etc. The values which these variables will take in the year in question have to be predicted, which leads to a type of uncertainty that is comparable to the residual variation discussed above. There is also the difficulty that models are never perfect, even apart from the random variation of the disturbances. They are estimated and the resulting coefficients are subject to sampling errors. There may also be specification errors: e.g., an equation may have been estimated in linear form whereas the "true" form is curvilinear.<sup>6</sup>

No approach is available which takes account of all these difficulties simultaneously. An attempt has been made by Theil to handle the uncertainty problem for given coefficients (without sampling and specification errors), but only for the case in which the decision-maker's preferences can be represented by a quadratic utility function. However, if this framework is accepted, the analysis can be extended rather far; in particular, the approach can be generalized to handle dynamic decision problems. This leads to a strategy or a decision rule according to which the appropriate values of the controlled variables are made dependent on the information which is or will be available at the moment when the relevant decision has to be taken. Several studies have been made dealing with macroeconomic applications of this approach [4, 5, 6, 7, 44, 45]. A related microeconomic set-up, dealing with production and work-force scheduling of a factory, has been worked out by C. C. Holt, F. Modigliani, J. F. Muth and H. A. Simon [13] and was reconsidered recently by C. Van de Panne [28, 29].

### *Quadratic Programming and the Optimal Use of Milk*

The final topic which I shall consider has also to do with decision-making and is also of the quadratic utility variety, but it is otherwise of a somewhat different nature. It deals with milk, of which too much is being produced in the Netherlands in the sense that the free-market

<sup>6</sup> For problems of specification and aggregation analysis, see [39, 40, 41]. See also Houthakker's comment [15] on Tinbergen's *On the Theory of Economic Policy* as well as Tinbergen's reply [47].

supply would exceed demand to such an extent that prices would not cover farmers' costs. This induced the Dutch government to subsidize farmers to an amount of more than 2 per cent of national income. Recently, S. L. Louwes, J. C. G. Boot and S. Wage [24] tried to design a policy by which this subsidy can be reduced. They distinguished between four products: consumption milk, butter, fat cheese, and meagre cheese (of which annual consumption will be denoted by  $x_1, x_2, x_3, x_4$  and prices by  $p_1, \dots, p_4$ ). Their objective was to maximize gross revenue,  $\sum p_i x_i$ , by an appropriate adjustment of prices. For this purpose they formulated linear demand functions, so that gross revenue becomes a quadratic function of prices:

$$(31) \quad Q(p) = a'p - \frac{1}{2}p'Bp,$$

where  $p$  is the price vector and  $a$  and  $B$  coefficient matrices, the former being of order  $4 \times 1$  and the latter a  $4 \times 4$  symmetric and positive-definite matrix. It is perfectly straightforward to maximize  $Q$  (the solution is  $p = B^{-1}a$ ), but the difficulty is that this solution implies a negative consumption of meagre cheese. It is, therefore, necessary to take account of appropriate constraints, which in this case take the form of linear inequalities. First, we have the nonnegative constraints on prices and quantities. Second, there are fat and dry matter requirements for each of the four products and these are also linear inequalities.

The problem is thus to maximize  $Q$  as defined in (31) subject to a number of constraints in linear inequality form, i.e., it is a quadratic programming problem. One might think that the unconditional maximum (which was reported above to violate one of the constraints) is worthless for the derivation of the constrained maximum; but this, as was shown in [46], is not the case. By imposing the violated constraint in equational form and proceeding in this way systematically, one can find the optimum after a number of steps.<sup>6</sup> In this case the solution is rather drastic compared with the observed present situation: the milk price should be doubled, the same applies to the price of fat cheese, the production of meagre cheese should be discontinued. Gross revenue is increased by such an amount that the increase in net revenue can be expected to make the government subsidy superfluous. However, the increase of consumer prices seems to be unacceptable from a social point of view. For this reason the authors decided to add a policy constraint according to which a weighted average of the relative increases in the prices  $p_1, \dots, p_4$  is not permitted to be larger than  $\pi$ , where  $\pi$  is a variable percentage. This is a problem of parametric programming and yields solutions for the optimal prices depending on  $\pi$ , i.e., depending on the degree to which one is willing to let the consumers of milk and milk products suffer.

<sup>6</sup> See also [8, 9, 10, 22].

Needless to say, this result is subject to a number of qualifications. No account is taken of uncertainty, the theory of stochastic programming being still in its beginning. To assume that the demand functions are linear is convenient because it leads to a quadratic objective function, but this is obviously only an approximation, particularly when prices are subject to sizable changes. In fact, these changes are sizable unless  $\pi$  is small; and since it seems plausible that the rate of change of demand with respect to price becomes smaller when the price becomes larger and larger, one may expect that the formulas used tend to underestimate the gross revenue of the solution.

## FOREWORD

The three essays appearing in this supplement of the *American Economic Review* are part of a series of papers recounting and assessing postwar developments in economic thought in leading professional centers where English is not the conventional language in use. This venture was made possible by a grant of the Ford Foundation to the American Economic Association. The Committee is pleased to be able to make these essays available to the membership.

In extending our invitation, the Committee asked each author to consider whether the impact of postwar policy problems had been significant to the development of thinking and research, or whether the evolution of professional work had taken a more detached course. We also urged him to concentrate upon a few major themes. Notwithstanding these suggestions, each author was given full freedom to develop his topic as he envisaged it. In consequence, each essay represents his personal judgment of what he considers to be the important developments in thought in the country or region with which he is concerned.

Since the end of World War II France has been faced with an exceptional variety of economic problems, including postwar reconstruction and bottlenecks, inflation and balance of payment difficulties, labor

problems, overseas wars and the loss of colonial territories, a series of nationalizations, the launching of nationwide planning, entry into the European Economic Community, etc. . . . As was to be expected, new policies have been developed to cope with at least some of these problems, and theorizing about the problems and policies has been abundant.

No choice of topics for survey from such rich material could do justice to the many contributors to French economic literature<sup>1</sup> in the postwar period. Forced to choose, and wishing to organize my review around a few widely-discussed topics rather than to enumerate individual endeavors, I have decided to survey the major contributions bearing on problems of resource allocation. This leaves out much more than is included<sup>2</sup> and results in a systematic bias for which my own tastes largely account. Indeed, this paper comes close to being a survey of contemporary quantitative economics in France. Considering the reservations of many French economists regarding the mathematical approach,<sup>3</sup> the bias is severe. I must admit it and accept the blame.

The bulk of this paper is divided into three largely independent sections. The first is devoted to a set of theoretical contributions that led to highly ingenious applications in the area of marginal cost pricing. The second covers some fundamental developments of the theory of intertemporal allocation. A few historical comments about the "French Marginalist School" serve as an introduction to these two sections. The third section describes the concepts and methods underlying the French approach to planning. It thus deals with public policy rather than with theory. To the extent that French planning has been more concerned with problems of resource allocation than with problems of economic stability, the main emphasis of this paper is maintained throughout the third section.

Each section can be read independently of the other two and to some extent is addressed to a different reader. The work surveyed in Sections I and II involves some rather technical and intricate arguments and relies heavily upon abstract theoretical concepts. The reader who has

wishes all members of the French economic profession to share his expression of deep gratitude, both for the stimulation he has received from their work and for the personal courtesies which have facilitated his task. He also presents sincere apologies for his grave sins of omission in writing this survey.

Professors Robert Strotz, Peter Pashigian, and George Hildebrand gave the author the benefit of their penetrating comments on the first draft of this paper. The editorial assistance of Miss Nancy Connolly at the University of Chicago has been immensely helpful.

<sup>1</sup> That literature is restricted, under the narrow definition adopted for this paper, to work done and published in *France* (not in *French*). After all, I live in Belgium. . . .

<sup>2</sup> Comprehensive surveys, that do not overlap much with the present selection may be found in James [74], André Marchal [99], Piettre [146], and in a way in *Encyclopédie française* [57] to which a large number of contemporary French economists have contributed.

<sup>3</sup> See, e.g., Piettre [147].

not kept abreast of the literature in the areas under review is thus advised to regard these two sections (which are largely self contained) as material better suited for patient study than for cursory reading. Section I further differs from Section II in that I have attempted to sketch the reasoning underlying the major propositions about marginal cost pricing, whereas the section on intertemporal allocation is essentially a statement of concepts and results. My motivation has been to provide the interested reader of Section I with enough details to familiarize him with a frame of reasoning and to enable him to reconstruct the whole argument, should he so desire.<sup>4</sup> The complexity of the material covered in Section II precluded any such attempt. As for Section III (which is again largely self contained), its more descriptive nature makes it more accessible—and there frustration is likely to arise as a consequence of the paucity rather than of the intricacies of analytical developments.

Anyone who is acquainted with French economics will wonder why the work of François Perroux and his associates at the "Institut des Sciences Economiques Appliquées" is not discussed here. I owe them and my English-speaking readers a special apology. Although I was planning to devote a section of this paper to the work of Professor Perroux, I finally felt so hopelessly unprepared for this task that I had to give it up. In the process I enjoyed some very stimulating readings and was led to meditate upon some particular difficulties in the dissemination of knowledge.

Writing about the neo-classical tools of analysis, Perroux warns us that, by their very design, they *deny us the right* to handle certain matters:

... ce sont les compétitions assez impures et imparfaites *pour exister*; les rendements croissants, sans quoi les oeuvres humaines seraient trop tranquilles pour être vraies; les liaisons différentes des seules liaisons de prix sans quoi il faudrait imaginer ce monstre: une croissance sans groupements de producteurs, sans profits liés, sans investissements directs; les inégalités entre sujets et entre groupes organisés, combattues, renaissantes qui construisent ou démolissent les architectures de leurs hiérarchies innombrables.<sup>5</sup>

Those are precisely the matters with which Perroux has been concerned in some 30 books and 300 papers published over the last 30 years, and

<sup>4</sup> The material surveyed in Section I is by and large arranged in order of increasing complexity of the problems, so that the demands placed upon the reader are also increasing.

<sup>5</sup> Perroux [143], p. 173; an *approximate* translation (traduttore, traditore!) goes as follows: "... they are: competitions sufficiently imperfect to exist; increasing returns, without which the works of man would be too steady to be real; non-price relationships, in the absence of which one should invent that monstrosity: growth without producers' coalitions, without joint profits, without autonomous investment; inequalities among subjects and organized groups, fought, revived, that build or break the structures of their countless hierarchies."

more particularly, in his major postwar publications.<sup>6</sup> Never deterred by the difficulty of the subject, he exhibits an original understanding of modern societies,<sup>7</sup> develops new concepts which go beyond external economies<sup>8</sup> or bypass interpersonal comparisons of utility,<sup>9</sup> and applies them to some of the most urgent problems of our times.<sup>10</sup>

These writings are always thought-provoking—ideas flow in all directions beyond familiar borders, and their expression is too rich to be altered. That such writings should defy summary is perhaps understandable. It is also understandable, but unfortunate, that contributions of this sort are so slowly and incompletely “assimilated” by the profession.<sup>11</sup> The tasks of recasting Perroux’s ideas in terms more familiar to most economists and of developing rigorously normative as well as empirically testable implications of his theories are indeed quite formidable. Yet it must be hoped that they will be carried out some day—for otherwise the contributions of a remarkably original thinker might well be partly lost.

### *The French Marginalist School*

During World War II two graduates from the “Ecole Polytechnique,” Maurice Allais and Pierre Massé, renewed a long tradition of contributions to mathematical economics started by Cournot and the engineer Dupuit a hundred years before and more recently maintained by such well-known econometricians as F. Divisia and R. Roy.<sup>12</sup> Allais published a treatise on economic analysis dealing with a closed non-monetary economy. His “social efficiency theorem” [3] stating the Pareto optimality properties of a competitive equilibrium<sup>13</sup> and the emphasis laid upon a general equilibrium approach to policy problems had a profound influence upon the thinking of young mathematical economists in

<sup>6</sup> Only three papers of Perroux [134, 138, 140] have appeared in English; [137, 142] are good introductions to further readings; [143] is an important collection of selected papers, of which an English translation would certainly be a welcome addition to many libraries.

<sup>7</sup> For instance, in his analysis of “domination”—see [132].

<sup>8</sup> “Development poles” and “progress foci”—see [137].

<sup>9</sup> “The costs of man”—see [135].

<sup>10</sup> In particular, problems of development—see [141].

<sup>11</sup> Perroux has trained a number of productive *disciples* and his influence on ideas and institutions has been great; but his impact on the economic literature (outside of his immediate followers) has been rather slight. Few, if any, of his ideas have ever been submitted to the hard test of prolonged professional debate at the empirical as well as theoretical levels.

<sup>12</sup> See Dupuit [56], Divisia [53]: “General Introduction: the contribution of French engineers to economics,” and the foreword of Lesourne [81].

<sup>13</sup> More recent developments, e.g., Debreu [47], generalize the theorem of Allais without significantly altering its scope; Thionet [156] gives a good summary and discussion of the theorem; Allais [4] sketches the proof.

France.<sup>14</sup> The comprehensiveness and wealth of original derivations<sup>15</sup> of that treatise, which was written under wartime conditions with very restricted access to the economic literature, are simply amazing. Some of its developments (e.g., the analysis of equilibrium when increasing returns to scale prevail in some industries)<sup>16</sup> have not become standard yet; others (e.g., the discussion of units of measurement)<sup>17</sup> bear upon problems of broad scientific interest outside of economics.<sup>18</sup>

At about the same time Massé [104 and 105] was investigating the optimal decision rule for operating a hydroelectric dam; among other things<sup>19</sup> he was led to formulate the "principle of optimality" of dynamic programming,<sup>20</sup> develop some general properties of stochastic marginal analysis,<sup>21</sup> generate horizon rules for a class of stochastic dynamic problems, and to handle problems of constrained optimization. This study, bearing upon a large class of economic problems under uncertainty,<sup>22</sup> established an early bridge between operations research (of which Massé was a precursor) and economic analysis; as such, as well as through the emphasis it put upon problems of dynamics and uncertainty, it also had a profound influence upon contemporary thinking in France.

Shortly after the war the problems of reconstruction and of management of the newly nationalized industries (electricity, gas,<sup>23</sup> coal mining) gave Allais, Massé, and their colleagues, students, or followers ample opportunities for applying and developing their theories. Allais [5] approached from the viewpoint of social efficiency some problems of transportation that also retained the attention of M. Boiteux [28] and of the research staff at the nationalized railroad company<sup>24</sup> where R. Hutter [70] displayed a continued interest in applied economic analysis.

<sup>14</sup> Allais has proudly reminded me that Debreu, Boiteux, Malinvaud, Nataf, Lesourne, Verhulst, Maillet, Nahon, . . . , are former students of his.

<sup>15</sup> For a summary account of these original developments, see the preface to the 1952 edition, pp. 18-33.

<sup>16</sup> See [3], pp. 304-305.

<sup>17</sup> See [3], pp. 220-267.

<sup>18</sup> Allais has published extensively in areas not covered by this survey, ranging from monetary theory [11] to physics [12] or politics [15].

<sup>19</sup> Thus Massé [105], Vol. II, pp. 8 ff., discusses informally an axiomatic concept of cardinal utility along lines parallel to the independent development of von Neumann and Morgenstern.

<sup>20</sup> As outlined, for instance, by Arrow [17], p. 525.

<sup>21</sup> See Massé [105], II, p. 39, for the important theorem on equality between the marginal utility of a flow and the marginal expected utility of the residual stock; also Massé [106 and 108].

<sup>22</sup> Mostly problems of inventory management or investment.

<sup>23</sup> The gas industry was studied by Verhulst [166 and 167].

<sup>24</sup> "Société Nationale des Chemins de Fer" (hereafter referred to as SNCF).

A subsequent study by Allais [7] of the management of the nationalized coal mines proved equally stimulating.<sup>25</sup>

At the same time Massé [107] was moving from the problems of operating policies to those of investment policy for the nationalized electricity industry;<sup>26</sup> the complementary aspects of those two classes of problems played an important role in many subsequent studies. His analysis of stochastic inventory problems led to further work by himself [109 and 110] and others (e.g., G. Kreweras [76]) as well as to a particularly significant and ingenious application by P. Gardent [61, 62] who derived a decision rule for the national production, import and inventory holdings of coal.<sup>27</sup>

At EDF substantial interest was focused at that time on the problem of marginal cost pricing, to which G. Dessus [52] and Boiteux were rapidly making important contributions.<sup>28</sup> By then what has sometimes been referred to as the French "marginalist" or "mathematical" school was born; an important stream of scientific activity was under way that has developed continuously ever since.

This development has been unusual in many respects. For one thing, it has taken place largely outside of the traditional professional circles and channels. Members of this "school" did and do belong to the staffs of the engineering schools or statistics departments, to the research as well as the executive divisions of the nationalized industries, or to the administration, but not to the staffs of economics departments or economic research institutes. Many important papers appeared in technological journals (especially journals catering to public utility problems) which the economic profession does not usually read. Actually most members of this "school" are graduate engineers (occasionally mathematicians), as were its initiators, and they have received limited formal training in economics. The main points of contact with general economists could have been the Econometric Society meetings and the seminars of Professors Allais, G. Guilbaud and Roy—but few general economists ever attend such meetings, for lack of interest and/or mathematical background. It is worth remarking that limited communication with the economic profession and literature does not seem to have significantly hindered the work of the marginalist or mathematical school.<sup>29</sup> One cannot help wondering whether such communication was

<sup>25</sup> It is noteworthy that these two applied studies of Allais [5 and 7] were conducted at the request of the nationalized railroads and coal mines respectively. Did Hicks ever work for the nationalized British industries?

<sup>26</sup> "Electricité de France" (hereafter referred to as EDF). The same problem was attacked by Gibrat [64].

<sup>27</sup> The work of Gardent is taken up by Massé [112], pp. 337-353 of the English text.

<sup>28</sup> For references, see Section I, p. 8.

<sup>29</sup> From the outset, however, communication has been excellent between this group and

perhaps adequately replaced by the close contact with reality which dominated much of the work here under review.

Indeed, the continued interaction between theory and practice has been another remarkable feature of these developments. While the pure theorist Allais was consulted about the management of the coal mines, Massé or Boiteux, who had executive responsibilities at EDF, developed original contributions to decision or price theory. The theorists and the executives fortunately shared the view that there is no sound policy unless it is based upon a sound theory, whereas empirical relevance and verification make for sound theories. The fact that so much work has been motivated by empirical problems and that it eventually led to practical applications may partly account for the soundness of the theories.<sup>30</sup>

Still there is one respect in which the engineering background of the research has resulted in a severe limitation. Much of the work surveyed in this paper belongs to "normative" rather than to "positive" economics.<sup>31</sup> That the normative analysis was developed first is quite natural. Yet empirical concern with the positive aspects of nationalizations, pricing policies, and planning would be very desirable at this stage; little work has been done along these lines. Accordingly, we are still lacking an objective evaluation of the actual incidence of postwar policies—either micro- or macroeconomic. Such an evaluation is obviously essential to further progress.

The bulk of the French contributions to the *theory* of resource allocation can conveniently be grouped under two headings, namely, those dealing with the management of a firm or industry and those dealing with the (general equilibrium) conditions of social efficiency. Under the first heading are mostly studies concerned with cost minimization, price-output decisions, and investment policy.<sup>32</sup> Of these three domains, the second only will be reviewed here (Section I). The third, to which belong important theoretical<sup>33</sup> as well as applied studies,<sup>34</sup> has recently been the

---

scientists in statistics and operations research. The connection with operations research, obvious in the case of Massé and more accidental for Allais [10], has been especially characteristic of the research divisions in the nationalized industries; some particularly brilliant contributions have come from SNCF, e.g., Matthys and Ricard [119].

<sup>30</sup> The exceptional intellectual qualities and close connections of people recruited (by contests) through the major engineering schools ("grandes écoles") has, of course, been another crucial factor.

<sup>31</sup> The most noteworthy exception to this statement is Allais; see, for instance, his interesting derivation of an objective test of rational management of the coal mines [7], Appendix 10; or the attempts at empirical testing of his monetary [11] and growth [13] models.

<sup>32</sup> Some studies escape this classification, in particular, those concerned with demand analysis for individual goods, of which remarkable instances are Mainguy and Mothes [90], or Mainguy and Nahon [91] for gas, and Morlat [122] for electricity.

<sup>33</sup> For instance, the surplus approach to investment decisions under increasing returns of Lesourne [80].

<sup>34</sup> In particular, the linear programming approach to electricity equipment policy over a

subject of a brilliant synthesis by Massé [112], now available in English.<sup>35</sup> As for cost minimization problems, they have been the subject of much applied research, most of which, however, falls rather in the province of operations research,<sup>36</sup> which is beyond the scope of the present survey.

Under the second heading the extensions of the theory of Pareto—optimality to intertemporal allocation and to uncertainty is first and foremost. Intertemporal allocation is the subject of Section II. The work on uncertainty (mostly concerned with decision-theory)<sup>37</sup> can be appraised through the proceedings of two symposia sponsored by the Centre National de la Recherche Scientifique [43, 46].<sup>38</sup> It is once more typical of the “French school” that work in this area has been influenced by practical problems (in particular, the treatment of risk and capital in the management of the nationalized utilities) and has been definitely less formal than the work in the same area by American economists.<sup>39</sup> However, the impact of that work on current orientation in the planning field is also beginning to be felt—as the final section of this paper indicates.

### I. *Marginal Cost Pricing*

#### *Concepts and Definitions*<sup>40</sup>

Much of the success of the French marginalist school in solving difficult practical problems in this area rests ultimately upon a sound and sometimes subtle understanding of the classical marginal cost concepts. Aside from the usual distinction between short-term and long-term cost curves, a further distinction between expansion and contraction costs has been repeatedly used.

Starting from the total cost curve for a given plant, its slope at any output defines the short-term marginal cost of that output. As plant sizes and designs vary, the envelope to the corresponding total cost curves defines a long-term total cost curve, whose slope at any output

12-year span at EDF—Massé and Gibrat [118]; Massé [112], Chap. IV, VIII; Bessière [24]; Boiteux and Bessière [38].

<sup>35</sup> The related problem of depreciation has been the subject of several studies by Boiteux; see, e.g., Boiteux [36] and Lhermite [84].

<sup>36</sup> See footnote 29 above, and issues of the *Revue Française de Recherche Operationnelle*, 1957 to date, for references.

<sup>37</sup> A paper by Allais [8] deals explicitly with the extension of general equilibrium theory to uncertainty. The “classics” on this subject are a paper by Arrow [16], available only in French to date, and a later paper by Debreu, written in Paris in 1953, and reprinted in Debreu [47]. See also Baudier [23].

<sup>38</sup> See also the general exposition of Massé [112], Ch. 5.

<sup>39</sup> A keen scrutiny of that literature, however, has been conducted by Nataf (unpublished notes) and Thionet [160 and 164].

<sup>40</sup> See Allais [7], Annex II, Boiteux [27], Section I.1., or Hutter [70], I.

defines the long-term marginal cost of that output. If the optimum output of a given plant is defined as that for which its (short-term) total cost curve is tangent to the long-term total cost curve,<sup>41</sup> then short-term marginal cost is higher than, equal to, or lower than long-term marginal cost according to whether actual output is larger than, equal to, or smaller than optimum output. However, for a plant of rigid capacity<sup>42</sup> short-term marginal cost is indeterminate at maximum output; hence, the relation of short-term to long-term marginal cost is also indeterminate at that output.<sup>43</sup>

In defining long-term marginal cost as the slope of the envelope, one implicitly assumes that changes in output take place in a way that constantly permits perfect adjustment of plant design to the quantity produced (so that equality between short-term and long-term marginal costs holds at every point in time). To the extent that actual plant variations will not meet this condition, actual costs of expansion ("development") or contraction ("regression") in plant capacity<sup>44</sup> will not be equal to long-term marginal cost and will also frequently not equal each other.<sup>45</sup> Hence the need for the concepts of "expansion cost" and "contraction cost"—whose importance lies not at all in the (classical) introduction of a "middle-term" marginal cost concept between the short-term and long-term ones but in the explicit recognition of an asymmetry between plant expansion and plant contraction. Two reasons account for this. On the one hand, some fixed costs to be incurred in case of expansion cannot be recouped in case of contraction. On the other hand, the old production unit that would be abandoned in case of contraction<sup>46</sup> may be technically very different from the new unit that would be used in case of expansion. Hence, the (marginal) cost relevant

<sup>41</sup> This amounts to defining the optimum output of a given plant as that output for which that plant is optimum, in the long run.

<sup>42</sup> That is, for a plant whose total, average, and marginal cost curves become vertical at a finite output.

<sup>43</sup> The slope of the total cost curve for a given plant may also fail to be defined due to the presence of indivisible expenditures (a typical situation in railroading); let total expenditures increase by  $\Delta E$  whenever output increases by  $\Delta O$ ; if actual output may be regarded as a random variable, the indivisible expenditure may be treated as adding  $\Delta E/\Delta O$  to short-term marginal cost at every output—as shown by Hutter [70], I, p. 57.

<sup>44</sup> I am using here the word capacity as short cut for "size and design" when plant capacity is not rigid.

<sup>45</sup> This raises a problem for investment policy, not for pricing policy; indeed, the theory of sale at marginal cost is primarily concerned with the short term marginal cost for the existing plant; it has been convincingly argued by Boiteux [27], Section 2.3., that the desire to keep prices stable leads, when the plant is for some reason not optimal, to the principle of setting prices equivalent to what short-term marginal costs would be if the plant were constantly of optimum size and design.

<sup>46</sup> This is, of course, the least profitable ("marginal") unit, be it a machine, or plant, etc (For instance, a passenger car, or train, or track, etc.)

for an expansion may *in principle* be lower than as well as higher than or equal to the (marginal) cost relevant for a contraction decision.

It is easily shown that only the latter alternative (expansion cost not lower than contraction cost) is consistent with a rational investment policy. Indeed, if the savings brought about by disposing of an old production unit were to exceed the corresponding costs incurred in procuring (and using) a new unit, then the old unit should be discarded and replaced.<sup>47</sup> This would presumably lower (or leave unchanged) the contraction cost (since the unit just discarded was the least profitable one) and raise (or leave unchanged) the expansion cost in the absence of economies of scale (since the unit just added was the least costly one). This process should continue until no further substitution of new for old equipment can be profitable, i.e., until expansion cost becomes equal to (or higher than) contraction cost.<sup>48</sup>

When expansion cost is higher than contraction cost, middle-term marginal cost is indeterminate, and explicit reference must be made either to expansion cost or to contraction cost.<sup>49</sup> As will be seen, such reference is frequently called for in practical applications of the theory of marginal cost pricing as well as in investment policy.

### *Peak-load Pricing*

The marginal cost pricing problem for a non-storable commodity with periodic demand fluctuations<sup>50</sup> is a special case of the pricing problem for multiple products.<sup>51</sup> As such, it is one of the most natural extensions of the standard theory of marginal cost pricing. It is also one of the most important applications of the theory to the management of public utilities (transportation, mail, telecommunications, and power supply). Furthermore, it brings out neatly the interactions between pricing and investment policies—two topics that will be surveyed together here.<sup>52</sup>

<sup>47</sup> The savings and costs must, of course, be defined on an appropriate basis. Typically, the problem is not one of deciding whether or not an old unit should be replaced but rather *when* it should be replaced. Hence, "an appropriate basis" is frequently provided by a comparison of present versus future replacement. The timing of contraction raises difficult problems, some of which are touched upon below (under *Marginal Cost Pricing and Investment Policy*, pp. 24 ff.).

<sup>48</sup> For a graphical treatment of this point, see Lesourne [81], pp. 274–5 of the English edition.

<sup>49</sup> For a skillful application of the concepts to coal mining, see Lesourne [82]; several unpublished papers by Boiteux and Dessus [EDF documents PR3-PR9, 1950] deal with marginal costs for various techniques of electricity production.

<sup>50</sup> Periodic *supply* fluctuations (e.g., due to seasonality of rainfall), raise basically analogous problems; see, for instance, Boiteux [27], Section 4 of the French text.

<sup>51</sup> Indeed, the output at various points in time of a given plant provide a perfect example of multiple products; the analysis for a storable commodity retains this essential feature, but involves inventory fluctuations as well as additional intertemporal efficiency conditions; see, e.g., Mills [121].

<sup>52</sup> Some general comments about these interactions are given below.

The main points of the original study by Boiteux [27]<sup>53</sup> may be summed up somewhat informally as follows.

Let us consider first the simplest cost situation, namely, that defined by (1) constant returns to scale, (2) fixed plant capacity (see footnote 42, p. 9 above) and (3) short-term marginal costs that are constant and that do not depend upon plant size. It is readily verified that under these three assumptions the (short-term) total cost function, for a plant of capacity  $q_0$ , must be of the form:

$$(1) \quad f(q_0, q) = \begin{cases} \beta q_0 + \gamma q, & 0 \leq q \leq q_0 \\ \infty & q > q_0 \end{cases}$$

where  $q$  is output per unit of time;  $\beta$  is a "marginal capacity cost";  $\gamma$  is short-term marginal cost; and  $\beta + \gamma = \delta$  is long-term marginal cost (= expansion cost).<sup>54</sup> The long-term total cost function may be written in the form:

$$(2) \quad F(q) = f(q, q) = \delta q, \quad q \geq 0.$$

This cost situation is depicted in Figure 1, where the long-term total cost function  $F(q)$  is plotted together with a set of short-term total cost functions  $f(q_0, q)$  (drawn for different values of  $q_0$ ).

The unit of time must, for our purposes, be such that demand fluctuations *within* any given unit are either non-existent or irrelevant.<sup>55</sup> It is then convenient to start the analysis with a graph (Figure 2) describing the "load-curve" (quantity demanded during each unit of time) corresponding to a uniformly set price equal to  $\gamma$ , the short-term marginal cost. The load curve is established for a *period* of  $T$  *units* of time, the shortest period over which demand exhibits recurrent fluctuations.<sup>56</sup> Thus, according to Figure 2, if the price  $p(h)$  charged at (during unit of) time  $h$  is equal to  $\gamma$ , for  $h = 1 \dots T$ , i.e., for the whole period, then the quantity demanded at time  $h$  will be  $q(h)$ . It reaches a peak  $q^+ = q(H)$  at time  $H$ .

It follows that if  $p(h) = \gamma$ ,  $h = 1 \dots T$ , then the peak load will actually be  $q^+$  and the plant capacity required to meet demand is also  $q^+$ . Remembering that our total cost function is defined "per unit of time," the total cost *per period* will be:

<sup>53</sup> The same problem was studied subsequently and independently by Houkhakker [69], Steiner [154] and Hirschleifer [68].

<sup>54</sup> Indeed,  $f(q, q) = \delta q$  by (1);  $f(q_0, q) = \infty$ ,  $q > q_0$ , by (2);  $f(q_0, q) = \delta q_0 - \gamma(q_0 - q) = \beta q_0 + \gamma q$ ,  $0 \leq q \leq q_0$ , by (1) and (3).

<sup>55</sup> Thus, in electricity supply, the unit of time might be one hour, or even less.

<sup>56</sup> Thus, in electricity supply, this period might be one day; the daily load curve will, of course, shift with the day of the week and the season of the year, but this adds little analytical difficulty to our problem.

$$\begin{aligned}
 (3) \quad \sum_{h=1}^T f[q^+, q(h)] &= \sum_{h=1}^T [\beta q^+ + \gamma q(h)] = T\beta q^+ + \gamma \sum_{h=1}^T q(h) \\
 &= (T\beta + \gamma)q(H) + \gamma \sum_{\substack{h=1 \\ h \neq H}}^T q(h).
 \end{aligned}$$

Total revenue for the same period will be:

$$(4) \quad \sum_{h=1}^T p(h)q(h) = \gamma \sum_{h=1}^T q(h),$$

leaving a deficit in the amount  $T\beta q^+$  for the entire period (or  $\beta q^+$  per unit of time—where  $\beta q^+$  is also the “total capacity cost” per unit of time).

*If the quantities demanded were independent of the prices charged*

$$\left[ \frac{\partial q(h)}{\partial p(i)} = 0, h, i = 1 \dots T \right]$$

then marginal cost pricing would call for prices  $p(h) = \gamma$  whenever  $q(h) < q^+$ , i.e., for  $h = 1 \dots T$ ,  $h \neq H$ ; the price  $p(H)$  would simply be subject to the inequality  $p(H) \geq \gamma$  since short-term marginal cost is indeterminate at  $H$  [for  $q(H) = q^+$ ]. However, it is readily seen from (3) that the partial derivative of total cost for the period with respect to  $q(H)$  is  $T\beta + \gamma$ —and this obviates the indeterminacy of short-term marginal cost at  $H$ . Accordingly, if  $p(H) = T\beta + \gamma$ , peak demand will be priced at its marginal cost (= short-term marginal cost + marginal capacity cost), and total revenue will rise to

$$(T\beta + \gamma)q(H) + \gamma \sum_{\substack{h=1 \\ h \neq H}}^T q(h).$$

The firm will thus break even, as was to be expected under our assumption of constant returns to scale.

This last implication is, of course, irrelevant *per se*: it is not part of the conditions defining marginal cost pricing. What is more relevant is the fact that plant capacity is optimal, in the sense that the revenue associated *at market prices* with the last unit of capacity, namely  $T\beta + \gamma$ , is precisely equal to the marginal cost of keeping ( $T\beta$ ) and using ( $\gamma$ ) that same unit. Should *this* equality fail to hold, then plant capacity should be adjusted (upward if marginal revenue at market prices exceeds marginal cost, downward in the opposite case).<sup>57</sup> The fact that a break-even situation automatically results from optimal pricing *and* investment policies (under our special assumption about costs and de-

<sup>57</sup> Indeed, capacity is just another input, and its marginal revenue product should equal its marginal cost, at market prices. The marginal revenue (of capacity) at market prices is simply the sum of the prices, over those periods where the last unit of capacity is utilized.

mand) serves as a convenient way of checking the joint optimality of these policies (and possibly also as a convenient way of implementing them).

Now let the quantity demanded at time  $h$ ,  $h=1 \dots T$ , be a function say,  $q[h, p(h)]$ , of the price  $p(h)$  charged at that time, but not of the prices  $p(i)$ ,  $i \neq h$ , charged at other times. Under these conditions, if  $p(H) > \gamma$ , the quantity demanded at that time,  $q[H, p(H)]$ , will be less than  $q^+ = q[H, \gamma]$ . The crucial question to ask when  $p(H) = T\beta + \gamma$ , is the following: Is  $q[H, T\beta + \gamma]$  less or not less than the next highest demand—which, in the example of figure 2, is  $q(H+1) = q[H+1, \gamma]$ ? Indeed, if  $q[H, T\beta + \gamma] \geq q[H+1, \gamma]$ , then setting plant capacity at  $q[H, T\beta + \gamma]$  and setting the prices at levels  $p(h) = \gamma$ ,  $h \neq H$ ,  $p(H) = T\beta + \gamma$  still provides a solution, with prices equal to marginal costs, capacity at its optimal level and total costs equal to total revenue for the period at the new level:

$$(5) \quad \gamma \sum_{\substack{h=1 \\ h \neq H}}^T q(h) + (T\beta + \gamma)q[H, T\beta + \gamma].$$

However, if  $q[H, T\beta + \gamma] < q[H+1, \gamma]$ , then under the price structure stated above, a plant capacity of  $q[H+1, \gamma]$  is called for, and short-term marginal cost becomes indeterminate at  $H+1$  but falls back to  $\gamma$  at  $H$ ! The latter pitfall could be bypassed by setting  $p(H)$  at whatever level—say,  $p^*(H)$ ,  $T\beta + \gamma > p^*(H) > \gamma$ —is required in order to peg the quantity demanded at time  $H$  at the new level  $q(H+1)$  of plant-capacity. Indeed, short-term marginal cost would then become indeterminate both at time  $H+1$  and at time  $H$  since  $q[H, p^*(H)] = q(H+1)$  by construction. Total cost would now be equal to

$$(6) \quad T\beta q(H+1) + \gamma q[H, p^*(H)] + \gamma \sum_{\substack{h=1 \\ h \neq H}}^T q(h)$$

and would exceed total revenue by an amount  $[T\beta + \gamma - p^*(H)]q(H+1)$  since total revenue would now be equal to

$$(7) \quad p^*(H)q[H, p^*(H)] + \gamma \sum_{\substack{h=1 \\ h \neq H}}^T q(h).$$

From (6) and (7) we can see that only a partial solution to the problem has been reached; indeed, the revenue associated, at market prices, with the last unit of capacity<sup>58</sup>—namely,  $p^*(H) + \gamma$ —falls short of covering the marginal cost of keeping that same unit and operating it during the two units of time  $H$  and  $H+1$ —namely,  $T\beta + 2\gamma$ . Plant capacity is thus excessive.

<sup>58</sup> See footnote 57, p. 13.

As plant capacity is further reduced below  $q(H+1)$ , both  $p(H)$  and  $p(H+1)$  have to be adjusted upward so as to peg the quantities demanded at times  $H$  and  $H+1$  at the new level of plant capacity—and the resulting revenue at market prices of the last unit of capacity has to be compared with the marginal cost of keeping and operating that same unit. Clearly, successive reductions of plant capacity will be associated with increased revenues at market prices—since the prices at times  $H$  and  $H+1$  will have to be raised in order to peg demand there at successively lower levels. The relevant marginal cost, on the other hand, remains constant by assumption so that the margin between the two amounts narrows. If that margin fails to vanish before the plant capacity is cut back to the level  $q(H-1)$  (see Figure 2), then the *three* prices  $p(H-1)$ ,  $p(H)$  and  $p(H+1)$  will have to be raised further, and capacity cut further. The introduction of period  $H-1$  into the calculation [for its contribution  $p(H-1) \geq \gamma$  to revenue at market price and its contribution  $\gamma$  to the marginal cost of the last unit of capacity that is now used during a third unit of time] can only speed up the narrowing of the margin. Eventually a level of capacity, say,  $\hat{q}$  on Figure 2, will be reached, such that, when  $p(h) = \gamma$  for all  $h$  where  $q[h, \gamma] = q(h) < \hat{q}$ , and  $p(h) = \hat{p}(h) \geq \gamma$  for all  $h$  where  $q(h) \geq \hat{q}$ , with  $\hat{p}(h)$  such that  $q[h, \hat{p}(h)] = \hat{q}$ , then:

$$(8) \quad \sum_{h=1}^T \hat{p}(h) = T\beta + \sum_{h=1}^T \gamma$$

$h \ni q(h) \geq \hat{q}$   $h \ni q(h) \geq \hat{q}$

(8) expresses precisely the equality between the marginal cost of keeping and operating the last unit of capacity (right side) and the associated revenue at market prices (left side).

Total cost for the period is now equal to

$$(9) \quad T\beta\hat{q} + \gamma \sum_{h=1}^T q[h, \hat{p}(h)] + \gamma \sum_{h=1}^T q(h)$$

$h \ni q(h) \geq \hat{q}$   $h \ni q(h) < \hat{q}$

$$= \left[ T\beta + \sum_{h=1}^T \gamma \right] \hat{q} + \gamma \sum_{h=1}^T q(h).$$

$h \ni q(h) \geq \hat{q}$   $h \ni q(h) < \hat{q}$

The corresponding total revenue is equal to

$$(10) \quad \sum_{h=1}^T \hat{p}(h)q[h, \hat{p}(h)] + \gamma \sum_{h=1}^T q(h)$$

$h \ni q(h) \geq \hat{q}$   $h \ni q(h) < \hat{q}$

$$= \hat{q} \sum_{h=1}^T \hat{p}(h) + \gamma \sum_{h=1}^T q(h).$$

$h \ni q(h) \geq \hat{q}$   $h \ni q(h) < \hat{q}$

In view of (8), the firm will again break even—a condition that could be used directly to locate  $\hat{q}$  if one so desired. Furthermore, substituting from (8) into (9) yields (10) as an alternative expression for total cost. The partial derivatives of (10) with respect to  $q(h)$ ,  $h=1 \cdots T$ , are either  $\gamma$ =short-term marginal cost where  $q(h) < \hat{q}$ , or  $\hat{p}(h)$  when short-term marginal cost is indeterminate (because the plant is operated at full capacity). Thus, all the prices reflect marginal costs.

Should one wish to solve the pricing problem for *given* plant capacity, it would clearly suffice to set  $\hat{q}$  equal to that capacity, and again to adopt prices  $\hat{p}(h)=\gamma$  where  $q(h) < \hat{q}$ ,  $\hat{p}(h)=\hat{p}(h)$  such that  $q[h, \hat{p}(h)]=\hat{q}$  where  $q[h, \gamma] \geq \hat{q}$ . A comparison of the marginal cost and the marginal revenue of capacity—see (8)—would then reveal whether existing capacity is excessive or defective.

Finally, let the quantity demanded at time  $h$  be a function of all prices  $p(i)$ ,  $i=1 \cdots T$ . Repeating step by step the argument just outlined, we must simply add that when  $\hat{p}(H)$  is set at a level higher than  $\gamma$ , not only will the quantity demanded at time  $H$  decrease, but the quantities demanded at other times will increase (decrease) by substitution (complementarity)<sup>69</sup> relative to the levels given in Figure 2 for  $\hat{p}(h)=\gamma$ ,  $h=1 \cdots T$ . The process of searching for a solution [prices  $\hat{p}(h)$  and capacity  $\hat{q}$ ] by successive approximations is not fundamentally different—only somewhat more laborious—to the extent that prices for different periods have to be adjusted *simultaneously* in order to peg demand during the peak interval (that now extends from  $H_1$  to  $H_2$  on Figure 2<sup>69a</sup>) at the constant level  $\hat{q}$ . The properties of the solution, however, are unchanged—prices are set equal to  $\gamma$  outside of the peak interval; the set of prices  $\hat{p}(h)$ ,  $h=H_1 \cdots H_2$  must be such as to jointly peg the demand at the constant level  $\hat{q}$  over that interval *and* below the level  $\hat{q}$  outside of that interval. The level  $\hat{q}$  of plant capacity is still determined by the condition (8) that now reads:

$$(11) \quad \sum_{h=H_1}^{H_2} \hat{p}(h) = T\beta + \sum_{h=H_1}^{H_2} \gamma.$$

This condition still implies that total cost for the period should be equal to total revenue. The interpretation of the prices  $\hat{p}(h)$  as marginal costs is unchanged; the pricing problem for *given* plant capacity would again be solved by setting  $\hat{q}$  equal to existing capacity.

In summary, peak-load pricing must be such as to both *depress* and *spread* the peak, while equating the marginal revenue at market prices and the marginal cost of keeping and using the last unit of capacity. Under our simple cost structure, the last condition automatically brings about a break-even situation. In principle, the pricing policy that meets

<sup>69</sup> Substitution will, of course, be the rule, complementarity the exception.

<sup>69a</sup> In general, the peak interval need not be continuous.

these conditions is determinate—there are as many conditions imposed upon the unknown prices and capacity as there are unknowns to determine—but no systematic analysis of existence and uniqueness of the solution has ever been published, to the best of my knowledge.<sup>60</sup>

Let us now consider briefly the consequences of relaxing our restrictive assumptions about costs. When plants do not have a fixed capacity, short-term marginal cost is well defined at all outputs, and prices  $p(h)$  must be equal to short-term marginal costs for all  $h$ . Accordingly, it will be typically impossible to keep output constant during a peak interval<sup>61</sup> and prices constant outside of that interval.<sup>62</sup> On the other hand, peaks may now be handled by overloading the plant so long as it is economical to do so, as well as by adjusting its size and design.

Although this need not complicate the pricing problem for a *given* plant size and design, it does complicate substantially the investment problem. The conditions of optimal investment can still be worked out mathematically, of course, but their economic interpretation and the accompanying rules of empirical implementation and verification become somewhat cumbersome. A special case of real practical interest<sup>63</sup> has been worked out by Boiteux. Let the total cost curves  $f(q_0, q)$  have the "congruence" property that short-term marginal costs are the same: (1) at output  $q$  for a plant with optimum output  $q_0$ ,<sup>64</sup> and (2) at output  $q+\epsilon$  for a plant with optimum output  $q_0+\epsilon$ ; and this for all  $q$  over the relevant range [that is,

$$\left. \frac{\partial f(q_0, q)}{\partial q} \right|_{\hat{q}} = \left. \frac{\partial f(q_0 + \epsilon, q)}{\partial q} \right|_{\hat{q} + \epsilon},$$

identically in  $\hat{q}$ ]. It can then be shown (cf. Boiteux [27], Mathematical Appendix) that the conditions of optimal investment require that *long-term marginal cost be equal to the average price* (= short-term marginal cost) *charged over the period*

$$\left[ \text{that is, } \left. \frac{\partial f(q_0, q)}{\partial q_0} \right|_{q=q_0} \text{ def } \left. \frac{\partial f(q_0, q)}{\partial q} \right|_{q=q_0} = \frac{1}{T} \sum_{h=1}^T p(h) \right].^{65}$$

This condition is, of course, very convenient for practical applications and it has been systematically used at EDF.<sup>66,67</sup>

<sup>60</sup> The subsequent studies [68, 69, 154] do not provide such an analysis either.

<sup>61</sup> A result that has come about so far because of the fixed capacity assumption.

<sup>62</sup> A result that has come about so far because of the constant short-term marginal cost assumption.

<sup>63</sup> At least in electricity supply—see footnote 67.

<sup>64</sup> See footnote 41 p. 9.

<sup>65</sup> In the general case, long-term marginal cost is a *weighted* average of the prices—the weights being functions of second-order partial derivatives of the cost function as well as of the elasticities and cross-elasticities of demand.

<sup>66</sup> See below under *Applications*, p. 34.

<sup>67</sup> In practice, the "congruence" assumption needs to hold only at the margin of the equip-

*Pricing under Stochastic Demand Conditions*<sup>68</sup>

Short-run fluctuations in demand occur frequently in random as well as in periodic patterns. In the case of a non-storable commodity,<sup>69</sup> the pricing problem raised by random fluctuations in demand is quite different from the problem of peak-load pricing. One might expect that, when the life of the equipment is long relative to the period over which demand exhibits significant fluctuations (around a known average), investment decisions would be guided by the same principles—no matter whether the fluctuations be random or periodic. As we shall see, this is not always so. As for pricing decisions, the basic difference is the following: peak-load pricing calls for a *known* periodic schedule of prices, whereas pricing at short-run marginal cost under stochastic demand conditions would call for *stochastic* price variations.

Stochastic short-run price variations are frequently ruled out on economic, administrative or legal grounds—and such has almost invariably been the case in the public utilities field. The combination of short-run price rigidity and short-run random fluctuations in demand must then result in a combination of (1) some form of demand rationing;<sup>70</sup> and (2) short-run fluctuations in output, to be met either by overloading a plant of flexible capacity or by building an adequate safety margin into a plant of fixed capacity. Both of these consequences are costly—either to the consumers or to the producers. Whenever consumers can reduce the amplitude of the short-run random fluctuations of their demand, it would obviously be desirable that the price structure induce them to do so. The question thus arises: Can some marginal cost (or “welfare loss”) be attached to the random variations of an *individual* consumer’s demand? If so, can a *non-stochastic* form of price discrimination reflect that marginal cost?

A satisfactory answer to that question is still missing, for lack of a workable extension to uncertainty situations of the theories of efficiency

ment. What matters is that additional investment should result in a *horizontal displacement* of the short-term marginal cost curve. Such would automatically be the case if the investment took the form of adding to the equipment a new unit of fixed capacity with low short-term marginal cost (so that it would be fully used throughout the period), or again, if the investment took the form of replacing some of several “congruent” old production units by more modern equipment. See the graphical illustration given by Boiteux, [34], p. 10, or [37], p. 92.

<sup>68</sup> Stochastic *supply* conditions raise related, but substantially different, pricing problems. See the brief comment of Boiteux [31], p. 226 and [37], p. 87.

I am grateful to Peter Pashigian for a very helpful discussion of the issues discussed under this heading.

<sup>69</sup> In the case of a storable commodity, such fluctuations will typically result in a combination of inventory, output and price variations—see, e.g., Mills [121].

<sup>70</sup> For example, queuing, priorities, quality deterioration, and so on.

and Pareto optimality.<sup>71</sup> Such an extension would indeed be needed in order to specify the *kind* of market prices that could bring about an efficient allocation of resources.<sup>72,73</sup>

Using a more pedestrian approach, Boiteux [29] has sketched a partial answer to our problem. His analysis rests upon the following assumptions: (a) the (short-term) total cost function, for a plant of capacity  $q_0$ , is of the form:<sup>74</sup>

$$(12) \quad f(q_0, q) = \begin{cases} \beta q_0 + \gamma q, & 0 \leq q \leq q_0 \\ \infty & q > q_0; \end{cases}$$

(b) there are a large number ( $N$ ) of individual consumers, each characterized by a demand (at a given time and price)  $q_i$ , a random variable with known expected value  $\bar{q}_i$  and (finite) variance  $\sigma_i^2$ ,  $i=1 \dots N$ . These random variables are "sufficiently analogously and independently distributed" (given the other elements of the problem) for aggregate demand to be approximately normally distributed with expected value

$$\bar{q} = \sum_{i=1}^N \bar{q}_i \quad \text{and variance} \quad \sigma^2 = \sum_{i=1}^N \sigma_i^2. \quad 75$$

Under these assumptions, the probability that aggregate demand will exceed a given level, say  $\bar{q} + k\sigma$ , can be read from a table of the standardized normal density function; conversely, to any positive probability  $\epsilon$  there corresponds a level of aggregate demand  $q(\epsilon)$  having probability  $1-\epsilon$  of not being exceeded, namely,  $\bar{q} + k(\epsilon)\sigma$ , where  $k(\epsilon)$  can be read from the same table.<sup>76</sup> Accordingly, *if a public utility were to operate under the constraint that it should be able to meet aggregate demand with probability  $1-\epsilon$ ,*<sup>76a</sup> it should then build a plant of capacity  $q_c(\epsilon)$ ,

<sup>71</sup> The references mentioned in footnote 37 above go some way toward providing a theoretical solution to this problem, but much remains to be done at the theoretical level and almost everything remains to be done at the level of applications.

<sup>72</sup> Two distinct allocation problems are at stake, namely, the allocation of *inputs* between this and other industries, and the allocation of *output* among consumers; the two problems are, of course, related.

<sup>73</sup> On this point, see the discussion by Allais, de Finetti, Kreweras, Marshack and Wold (pp. 227-230 in CNRS [43]) of some suggestions made by Boiteux [31]. Among other things, Boiteux suggests that each consumer might specify with what probability he expects his demand to be met, and what loss would result to him from lack of service; the producer would quote his price as a function of both the probability of service he is willing to guarantee and the penalty he would pay in case of shortage; why a public utility should sell insurance (or gambles!) as well as electricity is not altogether clear to me.

<sup>74</sup> This cost function was introduced above in equation (1) p. 11.

<sup>75</sup> This assumption involves reliance upon the "Central Limit Theorem"; Boiteux's paper does not develop or discuss formally the exact conditions imposed upon the individual demands.

<sup>76</sup> Thus,  $k(.025) = 1.96$ ,  $k(.005) = 2.58$ , etc.

<sup>76a</sup> The relaxation of that constraint is considered below.

and its total cost function would be, for outputs not exceeding  $q_o(\epsilon)$   
 $= \bar{q} + k(\epsilon)\sigma$ ;

$$\begin{aligned}
 f[\bar{q}(\epsilon), q] &= \beta q_o(\epsilon) + \gamma q \\
 &= \beta[\bar{q} + k(\epsilon)\sigma] + \gamma q \\
 (13) \quad &= \beta \left[ \sum_{i=1}^N \bar{q}_i + k(\epsilon) \left( \sum_{i=1}^N \sigma_i^2 \right)^{1/2} \right] + \gamma \sum_{i=1}^N q_i^*
 \end{aligned}$$

where  $q_i^*$  is the quantity actually sold to the  $i$ -th consumer. Thus,

$$q_i^* = q_i \text{ for all } i \text{ if and only if } \sum_{i=1}^N q_i \leq q_o(\epsilon).$$

Since no specific policy for handling shortages is considered, I shall assume that actual sales are proportional to individual demands, the factor of proportionality being 1 in the absence of shortage, and  $q_o/q$  in case of shortage.<sup>77</sup>

Total costs are thus a function of sales  $q_i^*$  and of two parameters of the density functions of individual demands—their means  $\bar{q}_i$  and either their variances  $\sigma_i^2$  or their standard deviations  $\sigma_i$ . Furthermore, it is readily verified that total costs are given by a non-linear function, homogeneous of the first degree in the quantities  $\bar{q}_i$ ,  $\sigma_i$  and  $q_i^*$ . The partial derivatives of (13), or “marginal costs,” are:

$$(14) \quad \frac{\partial f}{\partial \bar{q}_i} = \beta, \quad \frac{\partial f}{\partial \sigma_i^2} = \frac{\beta}{2} \frac{k(\epsilon)}{\sigma}, \quad \frac{\partial f}{\partial \sigma_i} = 2\sigma_i \frac{\partial f}{\partial \sigma_i^2} = \beta k(\epsilon) \frac{\sigma_i}{\sigma}, \quad \frac{\partial f}{\partial q_i^*} = \gamma.$$

Accordingly, if actual sales, expected demand and the *standard deviation* of demand are priced at marginal cost, consumer  $i$  should be charged an amount (incur an expenditure  $E_i$ ) equal to

$$(15) \quad q_i^* \frac{\partial f}{\partial q_i^*} + \bar{q}_i \frac{\partial f}{\partial \bar{q}_i} + \sigma_i \frac{\partial f}{\partial \sigma_i} = \gamma q_i^* + \beta \bar{q}_i + \beta k(\epsilon) \frac{\sigma_i^2}{\sigma} = E_i(q_i^*, \bar{q}_i, \sigma_i).$$

The total revenue to the utility is then

$$(16) \quad \gamma \sum_{i=1}^T q_i^* + \beta \sum_i \bar{q}_i + \beta \frac{k(\epsilon)}{\sigma} \sum_{i=1}^T \sigma_i^2 = \gamma q + \beta[\bar{q} + k(\epsilon)\sigma].$$

The utility will thus exactly break even—a result that is perhaps not surprising, under homogeneity of the first degree of the total cost function.

What happens if actual sales, expected demand and the *variance* of

<sup>77</sup> Actually, in the case of electricity supply, a shortage may take the form of a quality differential (lower tension) affecting all customers indiscriminately and entailing no measured discrepancy between the quantity sold and the quantity demanded.

demand are priced at marginal cost? From (14) we see that the  $i$ -th consumer should then be charged an amount equal to:

$$(17) \quad q_i^* \frac{\partial f}{\partial q_i^*} + \bar{q}_i \frac{\partial f}{\partial \bar{q}_i} + \sigma_i^2 \frac{\partial f}{\partial \sigma_i^2} = \gamma q_i^* + \beta \bar{q}_i + \frac{\beta}{2} k(\epsilon) \frac{\sigma_i^2}{\sigma} = E_i(q_i^*, \bar{q}_i, \sigma_i^2) \\ \leq E_i(q_i^*, \bar{q}_i, \sigma_i)$$

so that the utility's total revenue shrinks to:

$$(18) \quad \gamma \sum_{i=1}^N q_i^* + \beta \sum_{i=1}^N \bar{q}_i + \frac{\beta}{2} \frac{k(\epsilon)}{\sigma} \sum_{i=1}^N \sigma_i^2 = \gamma q + \beta \left[ \bar{q} + \frac{k(\epsilon)\sigma}{2} \right]$$

A deficit amounting to  $\frac{1}{2}\beta k(\epsilon)\sigma$  must now be faced: under marginal cost pricing of  $q_i^*$ ,  $\bar{q}_i$  and  $\sigma_i^2$  only half of the expenditures brought about by the excess capacity margin  $k(\epsilon)\sigma$  are covered.

This situation may seem to involve an element of ambiguity; indeed, it looks as if the *principle* of marginal cost pricing leaves room for indeterminacy when we come to *applications*. The ambiguity might be obviated by claiming that the combination of marginal cost pricing *and* constant returns to scale should result in a break-even situation—so that (15) and not (17) provides the right pricing formula. Whatever the reasons, this is also the formula advocated by Boiteux [29], Boiteux and P. Stasi [39] or F. Bessière [25] and applied by EDF (see, e.g., Boiteux [37]).

Surprisingly enough, a closer look at the problem reveals this choice to be erroneous. This can be seen as follows. From the marginal costs given under (14), we may compute the marginal rates of transformation for the producer:

$$(19) \quad \frac{\partial f / \partial \sigma_i}{\partial f / \partial \bar{q}_i} = - \frac{d\bar{q}_i}{d\sigma_i} \bigg|_{f=\text{const.}} = \frac{k(\epsilon)\sigma_i}{\sigma}, \\ \frac{\partial f / \partial \sigma_i^2}{\partial f / \partial \bar{q}_i} = - \frac{d\bar{q}_i}{d\sigma_i^2} \bigg|_{f=\text{const.}} = \frac{k(\epsilon)}{2\sigma}$$

Similarly, from the price formula (15) we may compute the marginal rates of substitution for the  $i$ -th consumer:

$$(20) \quad \frac{\partial E_i(q_i^*, \bar{q}_i, \sigma_i) / \partial \sigma_i}{\partial E_i(q_i^*, \bar{q}_i, \sigma_i) / \partial \bar{q}_i} = - \frac{d\bar{q}_i}{d\sigma_i} \bigg|_{E_i(\bar{q}_i^*, \bar{q}_i, \sigma_i) = \text{const.}} = \frac{2k(\epsilon)\sigma_i}{\sigma}, \\ \frac{\partial E_i(q_i^*, \bar{q}_i, \sigma_i) / \partial \sigma_i^2}{\partial E_i(q_i^*, \bar{q}_i, \sigma_i) / \partial \bar{q}_i} = - \frac{d\bar{q}_i}{d\sigma_i^2} \bigg|_{E_i(\bar{q}_i^*, \bar{q}_i, \sigma_i) = \text{const.}} = \frac{k(\epsilon)}{\sigma}.$$

Comparing the results under (19) and (20), we notice that *marginal cost pricing of sales, expected (or average) demand and the standard deviation of demand does not bring about equality between the marginal rates of*

*transformation and of substitution*—so that consumers will not substitute mean for variance (standard deviation) of their demands until their marginal rate of substitution becomes equal to the ratio of marginal costs. Thus, this pricing formula fails to accomplish a major goal of marginal cost pricing (efficient allocation of resources).

However, if we use price formula (17), the marginal rates of substitution are equal to the marginal rates of transformation—as the reader can easily verify—so that *marginal cost pricing of sales, expected demand and variance of demand leads consumers to substitute mean for variance until their marginal rate of substitution becomes equal to the marginal rate of transformation*, as desired. This is accordingly the correct application of the marginalist principles.

The appearance of a deficit under the correct pricing policy may be explained as follows. Under constant returns to scale in production, the *average* cost of meeting each individual demand with preassigned probability *decreases* when two groups of consumers, whose demands are *imperfectly correlated*,<sup>78</sup> may be considered as a single group for the purpose of planning excess capacity.<sup>79</sup> Indeed, denoting the standard deviations of the two groups by  $\sigma_1$  and  $\sigma_2$ , respectively, the covariance between the two groups by  $\sigma_{12}$  and the overall standard deviation by  $\sigma$ , we know that  $\sigma = (\sigma_1^2 + \sigma_2^2 + 2\sigma_{12})^{1/2} \leq \sigma_1 + \sigma_2$ , with equality arising if and only if  $\sigma_{12} = \sigma_1\sigma_2$  (or  $\rho_{q_1q_2} = 1$ ). Accordingly, the capacity level required to serve (with given probability of shortage) the overall group, namely,  $\bar{q} + k\sigma$ , is less than the sum of the corresponding capacity levels for the individual groups, namely,  $(\bar{q}_1 + k\sigma_1) + (\bar{q}_2 + k\sigma_2) = \bar{q} + k(\sigma_1 + \sigma_2)$ , whenever  $\rho_{q_1q_2} < 1$ . We thus see that *uncertainty about demand will typically transform* (technologically) *constant returns to scale into* (economically) *increasing returns to scale*<sup>80,81</sup> This is one more difficulty to be faced in extending general equilibrium analysis to uncertainty situations.

In order to complete the explanation, there remains only to point out that marginal cost pricing of  $q_i^*$ ,  $\bar{q}_i$  and  $\sigma_i$  results in a break-even situation (in spite of the implicit presence of increasing returns to scale) because it amounts to *price-discrimination*. Indeed, the standard deviations of individual demands are priced at a rate proportional to  $\sigma_i$  [see (14) and (15)], that is, at a rate that varies from consumer to con-

<sup>78</sup> When demands are not independent, the pricing problem is somewhat more complicated, but the reasoning in the text is still valid.

<sup>79</sup> In other words, when these two groups of consumers may be served from the same, as opposed from distinct, facilities.

<sup>80</sup> For another example of this phenomenon, see Manne [98].

<sup>81</sup> When demands are perfectly negatively correlated, constant returns to scale (at a lower average cost) may be restored—provided the variances of the two groups are equal. This limiting case is rather uninteresting but forces one to speak of “imperfectly correlated” demands instead of the more specific “not perfectly positively correlated” demands.

sumer.<sup>82</sup> There is, of course, no difficulty in covering costs under increasing returns to scale when this kind of price discrimination is regarded as an admissible policy.

In practice, the utility may neglect the discrepancy between the quantity demanded  $q_i$  and the quantity actually delivered  $q_i^*$ ,<sup>83</sup> and measure  $\bar{q}_i$  and  $\sigma^2_i$  by the average and variance of an individual consumer's demand over time. To these two parameters will correspond respectively the price parameters

$$\delta = \beta + \gamma \quad \text{and} \quad \zeta = \frac{\beta k(\epsilon)}{2\sigma}.$$

For any given  $\epsilon$ , the unknowns  $q_\epsilon$ ,  $\bar{q}$  and  $\sigma$  will then be determined simultaneously by the equation:

$$(21) \quad q_\epsilon = \bar{q} + k(\epsilon)\sigma, \quad \bar{q} = \sum_{i=1}^N \bar{q}_i(\delta, \zeta, \epsilon), \quad \sigma = \left[ \sum_{i=1}^N \sigma_i^2(\delta, \zeta, \epsilon) \right]^{1/2}.$$

Once more, questions of existence and uniqueness of the solution remain to be examined. In principle, a solution may exist for any  $\epsilon$ , so that  $\epsilon$  must be determined on independent grounds. Indeed, a reduction in  $\epsilon$  may be viewed as an improvement of the quality of the product. Since by construction only half the cost of the improvement will be borne by customers, the profitability of the required investments cannot serve as a guide here. A market solution would probably exist if the probability of shortage  $\epsilon$  could be varied [together with the price  $\zeta(\epsilon)$  attached to variance] from one individual to the next.<sup>84</sup> Short of achieving such flexibility, some estimate of the consumer's surplus associated with variations of  $\epsilon$  would be needed in order to choose a probability of shortage.<sup>85</sup>

Unsatisfactory as the treatment of this problem may be, it has at least the merit of bringing into sharper focus some very real difficulties that

<sup>82</sup> By contrast, it should be remembered that peak-load pricing results in prices that vary over time but apply identically to all consumers. See also the comments on this point by Hirschleifer [68]. This particular form of price discrimination also explains why the marginal rate of substitution in (20) differs from the price ratio.

<sup>83</sup> As was pointed out in footnote 77, this discrepancy may be difficult to measure; it will at any rate be small when  $\epsilon$  is itself small.

<sup>84</sup> Some discussion of that problem is offered by Boiteux [29], but the general problem remains to be attacked.

<sup>85</sup> The same indeterminacy would arise if the problem were stated in terms of a fixed plant capacity  $q_\epsilon$ —a statement that might be appropriate for short-term analysis. Let a unit of capacity be valued at the "shadow-price"  $\hat{\beta}$ , so that the parameters of the price policy become

$$\delta = \hat{\beta} + \gamma, \quad \zeta = \frac{\hat{\beta} k(\epsilon)}{2\sigma}$$

and the parameters of aggregate demand become  $\bar{q}(\delta, \zeta, \epsilon)$ ,  $\sigma(\delta, \zeta, \epsilon)$ ; for any arbitrary value of  $\epsilon$  one should now investigate the existence (and uniqueness) of a value  $\hat{\beta}$  such that  $\bar{q}(\delta, \zeta, \epsilon) + k(\epsilon) \sigma(\delta, \zeta, \epsilon) = q_\epsilon$ . In principle, a solution may exist for any  $\epsilon$ —so that fixing plant capacity does not eliminate the indeterminacy of the quality parameter.

arise when one attempts to apply marginal analysis to uncertainty situations. The added difficulties connected with increasing returns are discussed further under the next two headings.

*Marginal Cost Pricing, Budget Balancing and Investment Policy*

When marginal costs are decreasing, as for instance in railroading, marginal cost pricing inevitably leads to a deficit. Yet the condition of budget balancing has also been advocated by Boiteux [28] as implying an optimal *disinvestment* policy for the railroad industry. The argument runs as follows:

Consider a particular railroad line, with given existing facilities, that is subject to competition from road carriers. It simplifies exposition, without significantly altering the nature of the problem, to assume that the supply of road transportation services is perfectly elastic at the price  $p^{86}$  equal to minimum long-run average cost for road carriers. Accordingly,  $p$  provides an upper limit for the prices to be charged, and marginal costs to be incurred, by the railroad. Let furthermore the demand for transportation services at price  $p$  generate a total revenue per unit of time in the amount  $\gamma$ —the assumption that revenue is constant over time, entailing again no significant loss of generality.

If the transportation services demanded at price  $p$  can be supplied by the railroad at a *full* cost, including adequate replacement charges on *all* its equipment (tracks, stations, rolling stock, . . .) that does not exceed  $\gamma$  per unit of time, then it will be economical to operate the railroad indefinitely. Road transportation will then come in only when the railroad is saturated.<sup>87</sup>

If, on the other hand, the full cost to the railroad exceeds  $\gamma$  per unit of time, but the variable cost (excluding replacement charges) does not, then the line will ultimately have to be abandoned, and the traffic diverted to road carriers. In that case, *some but not all* replacements of railroad equipment are economical (e.g., the costs of replacing the rolling stock periodically can be absorbed, but not those of replacing the tracks). Two questions must then be answered. What replacements are economical? When should the line be abandoned? Clearly, these two questions must be answered simultaneously—and the answers will also depend upon the pricing policy adopted by the railroad while in operation. Again, it will simplify exposition without altering the nature of the problem if we assume that prices will be set at the level  $p$  immedi-

<sup>86</sup>  $p$  is typically a *vector* of prices for differentiated services (first and second class passenger transportation, a schedule of commodity rates, etc.); whenever price, or  $p$ , is mentioned in the text, a vector interpretation is implicit.

<sup>87</sup> Alternatively, road services may be introduced for different kinds of traffic, excluded from the present analysis.

ately. This policy will typically maximize revenue for the railroad<sup>88</sup> while providing its customers with information about the long-run equilibrium price level.<sup>89</sup>

We may now compute, for *each* future date  $T$ , the *present* value of the *minimum* cumulated total cost  $M_T$  of keeping the railroad in operation until  $T$  and not later. Thus consider first the value of time 0,  $V_0$ , of the equipment in use at that time;  $V_0$  is an opportunity cost equal to the net savings that would accrue to the railroad from using some of that equipment elsewhere, plus the resale value on the market of the equipment for which the railroad would have no economical use elsewhere. Next consider the minimum costs of operation, at the traffic level corresponding to  $p$ , during periods  $t=1 \cdots T$ , say,  $\delta_t(T)$ ;<sup>90</sup> these costs include appropriate replacement charges for all those pieces of equipment that it will *pay to replace knowing that the line is to be abandoned at  $T$* .<sup>91</sup> The dependence of the replacement decisions upon the date of abandonment is, of course, the reason for expressing these costs as a function of  $T$ . Finally, let  $V_T$  stand for the value of the equipment (old and new) at time  $T$ . Then:

$$(22) \quad M_T = V_0 - \frac{V_T}{(1+i)^T} + \sum_{t=1}^T \frac{\delta_t(T)}{(1+i)^t}.$$

where  $i$  is the appropriate discount factor.<sup>92</sup>

This expression may be compared (for given  $T$ ) with the alternative cost, namely, the present value of the cumulated costs of an equal amount of road transportation services. Under our assumptions, that cost is also the revenue to the railroad, say  $R_T$ , if it charges the price  $p$  from now on.  $R_T$  is thus defined as follows:

$$(23) \quad R_T = \sum_{t=1}^T \frac{\gamma}{(1+i)^t}$$

In Figure 3, both  $M_T$  and  $R_T$  are graphed—as functions of  $T$ —so as to reflect a situation where the *full* cost to the railroad exceeds  $\gamma$  per unit of time (the asymptotic value of  $M_T$  exceeds that of  $R_T$ ).

Boiteux argues that the railroad should be kept in operation until, but not beyond, the time  $\theta$  at which  $M_\theta = R_\theta$ . The fact that, for any  $T < \theta$ ,

<sup>88</sup> The demand curve for the railroad has a kink at  $p$ —in view of road competition.

<sup>89</sup> This is the more relevant information for location decisions, for instance.

<sup>90</sup> Thus, the  $t$ -th period runs from time  $t-1$  until time  $t$ .

<sup>91</sup> And given their opportunity or market value at  $T$ ; such replacements may be regarded as “defensive investments.” See Lamfallussy, [77].

<sup>92</sup> What discount factor should be used by the nationalized industries has been the subject of much thought and debate. See, e.g., the discussion by Allais and Boiteux, pp. 86 and 98 in CNRS [46], and the treatment by Massé [112].

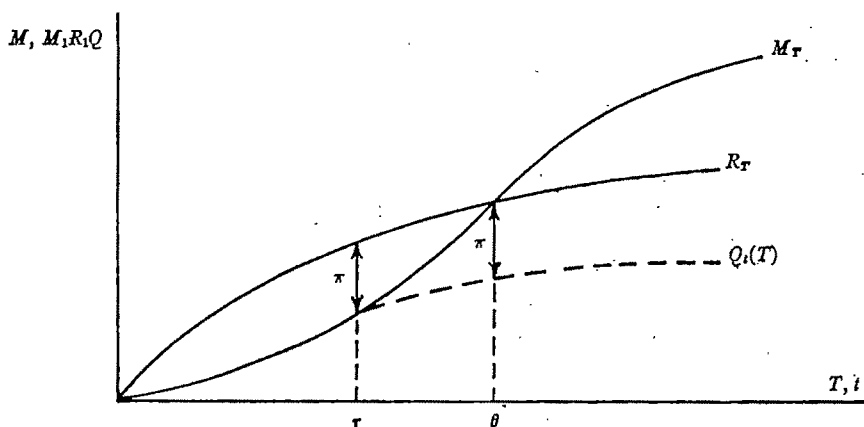

FIGURE 3

$M_T < R_T$  is taken as an indication that the railroad is more economical than road transportation there—and conversely for  $T > \theta$ . Since the total revenue to the railroad, at prices kept equal to  $p$  over the period  $0-\theta$ , has a present value  $R_\theta$ , it follows that abandoning the line at time  $\theta$  is financially equivalent to abandoning it immediately. If the condition is imposed on the railroad to break even, insofar as this particular line is concerned,<sup>83</sup> with a capital charge  $V_0$ , it has no choice but to *decide now* to abandon the line either immediately or at time  $\theta$ . Hence the break-even condition, it is claimed, leads to an optimal disinvestment policy.

The conclusion would certainly be correct if it were indeed so that  $\theta$  is the optimal time at which to abandon the line. However, such is not the case: the optimal time,  $\tau$ , is not defined by the condition  $M_T = R_T$  but rather by the condition

$$(24) \quad \frac{\partial M_T}{\partial T} = \frac{\partial R_T}{\partial T},$$

Indeed, define

$$(25) \quad Q_i(T) = M_T + R_i - R_T = M_T + \gamma \sum_{s=T+1}^i \frac{1}{(1+i)^s}, \quad i > T$$

as the total cost to the community of providing the transportation services demanded at prices  $p$  up to time  $i$ , if the railroad is kept in operation until the time  $T$  (at which road transportation takes over). Minimizing  $Q_i(T)$  with respect to  $T$  calls for condition (24), the eco-

<sup>83</sup> Boiteux discusses the relation between breaking even in the economic sense under discussion here and in the accounting sense. The difference between "economic" and "accounting" costs can be sizeable when long-lived investments are involved and the country is experiencing severe inflation.

nomic interpretation of which is that the railroad should be kept in operation so long as the *marginal* cost of extending its life by one period is less than the *alternative* cost of switching to road transportation. (By contrast, Boiteux compares the *total* cost of operating the railroad to its alternative.) In this sense optimal disinvestment policy is still governed by marginalist principles<sup>94</sup>—but it does not entail breaking even.

Indeed, the present value of total revenue up to time  $\tau$ ,  $R_\tau$ , exceeds the present value of total cost,  $M_\tau$ , by an amount  $\pi = \text{MAX}_t (R_t - M_t)$ . Thus, the current value of the equipment to the railroad may be set equal to

$$(26) \quad V_0 + \pi = R_\tau - \sum_{t=1}^{\tau} \frac{\delta_t(\tau)}{(1+i)^t} + \frac{V_\tau}{(1+i)^\tau},$$

which is its value under optimal use. To say that this particular line would break even if the equipment were currently valued at  $V_0 + \pi$  would, of course, beg the question.

What pricing policy should be adopted under condition of budget balancing will be reviewed next.

#### *Welfare Pricing under a Budget Balancing Constraint*

What should a public utility do when marginal cost pricing leads to a deficit but the utility is under legal obligation to balance its budget?<sup>95</sup> Several solutions to that problem have been advocated. Prior to World War II, the pricing policy of the French railroads was based upon the principle of price discrimination advocated by Colson [42]: tariffs *ad valorem* were the rule—this being supposedly equivalent to taxing inelastic demands and subsidizing elastic demands—except when the pressure from other means of transportation imposed competitive prices. Reacting against this practice, Allais advocated in his early transportation study [5] that all prices should be *proportional to marginal costs* irrespective of demand elasticities. The factor of proportionality would be so chosen as to bring about a break-even situation. This solution was presented by Allais as a “first approximation” to a “lesser evil.” Indeed, he indicated a theoretical preference for the “Hotelling solution,” i.e., marginal cost pricing and a government subsidy equal to the deficit; but he declared that solution psychologically (i.e., politically?) un-

<sup>94</sup> The equipment will indeed be used until marginal cost is equal to marginal revenue at market price—a situation that obtains at time  $t$ ; “marginal” is defined here in terms of time periods; that is, the unit of quantity is one time-period’s output.

<sup>95</sup> The analysis in this section applies also to the case where marginal cost pricing leads to a positive profit, but the utility is under legal obligation to pass its profits on to consumers via price reductions. It is not altogether clear that second-order conditions would be satisfied in both cases—a problem that remains to be investigated.

feasible and economically inadvisable—for lack of appropriate incentives to cost minimization in the absence of a budget restriction. The main argument put forward by Allais in favor of this proportionality rule was ease of application.<sup>96</sup> This, and the alleged advantages of keeping the ratio of two prices equal to the ratio of the corresponding marginal costs, is also the reason why he continued at a later date to prefer the principle of proportionality (of prices to marginal costs) to the following alternative solution which he then regarded as more appealing: namely, to introduce whatever price discrimination is called for, to the effect that prices of *consumer goods only* be proportional to “what they would be under generalized marginal cost pricing.”<sup>97</sup>

After further contributions by Boiteux [30] and Debreu [48] in the surplus tradition, a more satisfactory treatment was introduced by Boiteux [33] who used a “second best” approach.<sup>98</sup> Boiteux studied an economy consisting of two “sectors,” a “competitive” sector where marginal costs and marginal productivities are equated to market prices, and a “public” sector (consisting of either a single or several firms) where the same equalities hold with respect to a set of “shadow prices” that need not correspond to market prices but must be such that the public firm breaks even under the rules just mentioned. Boiteux studied the first-order conditions of constrained Pareto optimality for such an economy. Those conditions turned out to be derivable and susceptible of a reasonably straightforward interpretation, at the cost of some ingenuity.

In the case of a single budget constraint (imposed upon a single public firm, or alternatively upon the public sector as a whole), the analysis runs as follows.

Let there be  $m$  consumers,  $v$  firms belonging to the private sector and  $n$  goods or services, with market prices  $p_i$ ,  $i = 1 \dots n$ . The net quantities of good  $i$ , respectively, bought by consumer  $k$  and sold by firm  $h$  are denoted by  $q_i^k$  and  $\chi_i^h$ ,  $i = 1 \dots n$ ,  $k = 1 \dots m$ ,  $h = 1 \dots v$ . The consumption of consumer  $k$  is restricted by the budget constraint

$$(27) \quad \sum_{i=1}^n p_i q_i^k = r^k \quad k = 1 \dots m$$

<sup>96</sup> A sketchy theoretical derivation given in footnote (3), p. 10 of Allais [5] is unconvincing and was not referred to by the author in subsequent discussions.

<sup>97</sup> See Allais [7], p. 101; see also further comments by Allais in the preface to Lesourne [81], p. XXIII. Whether the later solution could be made operational has not been established.

<sup>98</sup> This approach was independently discussed at the same time by Lipsey and Lancaster [85]. Boiteux's analysis of a specific second best problem is carried out within a more complete and general model; as such, it remains—to the best of my knowledge—the fullest treatment of a second best problem in the literature to date.

The production of firm  $h$  is constrained by the production function

$$(28) \quad f^h(x_1^h, \dots, x_n^h) = 0.$$

The public firm (sector) sells the net quantity  $y_i$  of good  $i$ ,  $i=1 \dots m$ . Its production is constrained by the production function

$$(29) \quad g(y_1, \dots, y_n) = 0$$

whose partial derivatives  $\partial g / \partial y_i$  will be denoted by  $g_i$ ,  $i=1 \dots n$ .

The market clearing conditions are thus

$$(30) \quad y_i = \sum_{k=1}^m q_i^k - \sum_{h=1}^v x_i^h \quad i = 1 \dots n.$$

Together they imply that the sum of the transfer and property incomes of the consumers,  $r^k$ , be equal to the net profits of the private and public firms:<sup>99</sup>

$$(31) \quad \sum_{i=1}^n \sum_{k=1}^m p_i q_i^k = \sum_{k=1}^m r^k = \sum_{i=1}^n p_i y_i + \sum_{i=1}^n \sum_{h=1}^v p_i x_i^h$$

To these traditional conditions is now added a budget constraint for the public firm:

$$(32) \quad \sum_{i=1}^n p_i y_i = b$$

where  $b$  is some given number (possibly 0). First-order conditions for Pareto optimality are then derived, under the foregoing conditions (29), (30), (32), and the assumptions that (1) all consumers maximize their satisfaction, given their budget constraints (27) and (2) all private firms maximize their profits, given their production functions (28) and *given the market prices*  $p_1 \dots p_n$ .<sup>100</sup> The parameters to be determined by these first-order conditions are the  $n$  prices  $p_1 \dots p_n$ , the  $n$  public outputs  $y_1 \dots y_n$  and the  $m$  transfers  $r^1 \dots r^m$ —i.e.,  $2n+m$  parameters constrained by the  $n+2$  relations (29), (30) and (32). There are accordingly  $m+n-2$  “free” parameters in the system.

After eliminating (by means of the relevant first-order conditions) the  $m$  transfer parameters  $r^k$ , Boiteux shows that the remaining first-order conditions consist of (29), (32) and the following:<sup>101</sup>

$$(33) \quad \sum_{i=1}^{n-1} \left( g_i \frac{p_n}{g_n} - p_i \right) (ij) = \beta y_j, \quad j = 1 \dots n-1$$

<sup>99</sup> (31) is obtained by multiplying both sides of (30) by  $p_i$  and summing over  $i$ .

<sup>100</sup> Thus monopolistic exploitation is ruled out as well as external economies in production or consumption.

<sup>101</sup> My conditions (33) are the conditions (22) of Boiteux [33], p. 31, after correcting for an error of sign and adopting a different normalization rule; the error of sign arises from condi-

where:

$$(34) \quad (ij) = \sum_{k=1}^n \left( \frac{\partial q_i^k}{\partial p_j} + q_j^k \frac{\partial q_i^k}{\partial r^k} \right) - \sum_{k=1}^n \frac{\partial x_i^k}{\partial p_j}$$

is the partial derivative with respect to the  $j$ -th price of the *compensated* demand function for the public firm's output of the  $i$ -th good; and where  $\beta$  is a constant that must be chosen so as to bring about compatibility among the conditions (29), (32) and (33).<sup>102</sup>

The interpretation of (33) goes as follows: Let  $\pi_i, i=1 \dots n$  denote the shadow prices to which the public firm equates marginal costs and productivities. Using the  $n$ -th good as numéraire,<sup>103</sup> we may set  $p_n = \pi_n$  and write the marginal conditions as follows:

$$(35) \quad \frac{g_i}{\pi_i} = \frac{g_n}{\pi_n} = \frac{g_n}{p_n}, \quad i = 1 \dots n-1.$$

Accordingly,

$$(36) \quad g_i \frac{p_n}{g_n} - p_i = \pi_i - p_i = t_i, \quad i = 1 \dots n,$$

which defines  $t_i$  as the discrepancy between the shadow price and the market price of good  $i$ ;  $t_i$  may thus be interpreted as a "toll" levied by the public firm on good  $i$ , or alternatively, as the tax that should be imposed on the public firm's sales or purchases of good  $i$  in order to bring about equality between marginal costs and productivities on the

tions ( $\partial p_i$ ) and ( $\partial y_i^k$ ), *loc. cit.*, pp. 28-29, that give to  $\beta^k$  incompatible signs; I have corrected in ( $\partial p_i$ ) by changing all the signs in the conditions ( $\beta^k$ ), p. 28; the correction affects furthermore the last line of p. 28 and conditions (16), (18), (20), (22) and (24). The correction also led me to replace the normalization " $p_n = -\mu_n$ ," at the top of p. 30 by the alternative: " $p_n (1-\beta) = \mu_n$ ," which entails certain other advantages. Other misprints in [33] include the following: condition (14), p. 28, should read:

$$\sum_i p_i (ij)^k = 0;$$

conditions ( $\mu_i$ ), p. 28, should read:

$$\sum_k q_i^k(P, r^k) - \sum_k x_i^k(P) - \sum_k y_i^k = 0;$$

conditions ( $\partial y_i$ ), p. 29, should read:  $\mu_i = \phi^i g_i^i + \beta^i p_i$ .

<sup>102</sup> Actually,

$$\beta = \frac{p_n}{b - p_n y_n} \sum_{i=1}^{n-1} \left( p_i - g_i \frac{p_n}{g_n} \right) (in).$$

If the  $n+1$  parameters  $y_1, \dots, y_n$  and  $\beta$  are determined by (29), (32) and (33), then equations (30) can be solved for the prices, and the transfers can in turn be determined from the relations (not reproduced here) on the basis of which they were eliminated.

<sup>103</sup> It is implicit in the statement of the problem that *every one* of the  $n$  goods enters, either as an input or as an output, in the public firm's production function (29). One of the accounting prices may thus be chosen arbitrarily.

one hand and market prices net of taxes on the other hand.<sup>104</sup> Thus, (33) is a set of  $n-1$  equations that are linear in the  $n-1$  unknown tolls  $t_i$ ,  $i=1 \dots n-1$ :

$$(33') \quad \sum_{i=1}^{n-1} t_i(ij) = -\beta y_j \quad j = 1 \dots n-1.$$

Boiteux gives an interpretation of these conditions by showing that the tolls must be proportional to the (market) price differentials that would bring about *identical relative* differentials of the *compensated* demands (supplies) to the public sector. He regards this property as being the most natural starting point for empirical application of the conditions. Such applications would be facilitated by the important (and eminently sensible) further property that, for perfect substitutes, relative tolls should be identical (hence, absolute tolls proportional to marginal costs).<sup>105</sup>

A somewhat more direct interpretation of these conditions comes from noting that a profit maximizing policy on the part of the public firm would call for the first-order conditions.<sup>107</sup>

$$(37) \quad \sum_{i=1}^{n-1} \left( g_i \frac{p_n}{g_n} - p_i \right) \frac{\partial y_i}{\partial p_j} = y_j \quad j = 1 \dots n-1.$$

<sup>104</sup> Boiteux shows explicitly that the shadow prices  $\pi_i$  are also the marginal costs and productivities, when the latter are again computed in terms of the shadow prices. Thus, if good  $i$  is produced by the public firm, then  $\pi_i$  is its marginal cost in terms of shadow factor prices.

<sup>105</sup> The conditions can also be written in terms of relative tolls and "compensated" elasticities:

$$(33'') \quad \sum_{i=1}^{n-1} \frac{t_i}{p_i} \left[ -\frac{p_i}{y_i} (j i) \right] = \beta, \quad j = 1, \dots, n-1.$$

Indeed,  $(i j) = (j i)$ . See Boiteux [33], pp. 27-28. The reader may find it instructive to work out the implications of (33'') for the special case where  $(j i) = 0$ ,  $i \neq j$ .

<sup>106</sup> The situations typically referred to by Allais are not too remote from this case; indeed, he refers quite naturally to alternative means of transportation or sources of energy in discussing the merits of his policy recommendations; see footnote 97.

<sup>107</sup> Indeed, if one solves (29) explicitly for  $y_n = y_n(y_1 \dots y_{n-1})$ , so that

$$\frac{\partial y_n}{\partial y_i} = -\frac{g_i}{g_n}$$

and uses again  $p_n$  as a numéraire, the profit maximization problem becomes:

$$\text{Max}_{p_1 \dots p_{n-1}} \sum_{i=1}^{n-1} p_i y_i + p_n y_n(y_1 \dots y_{n-1}) = F(p_1 \dots p_{n-1})$$

The first order conditions are then:

$$\frac{\partial F}{\partial p_j} = y_j + \sum_{i=1}^{n-1} p_i \frac{\lambda y_i}{\partial p_j} + p_n \sum_{i=1}^{n-1} \frac{\partial y_n}{\partial y_i} \frac{\partial y_i}{\partial p_j} = 0, \quad j = 1, \dots, n-1.$$

These conditions are equivalent to (37) where

$$\frac{\partial y_n}{\partial y_i} \text{ has been replaced by } -\frac{g_i}{g_n}.$$

Thus, the first-order conditions for the constrained Pareto optimum differ from those for profit maximization by: (1) the introduction of the constant  $\beta$  on the right-hand side; and (2) the replacement of the partial derivatives  $\partial y_i / \partial p_j$  by the corresponding partial derivatives ( $ij$ ) of the *compensated* demand functions on the left-hand side.

The most natural way to introduce  $\beta$  in the profit maximization conditions (37) consists of replacing

$$\frac{\partial y_i}{\partial p_j} \text{ there by } \frac{1}{\beta} \frac{\partial y_i}{\partial p_j}; \text{ for } 1 > \beta > 0,^{108}$$

this would amount to saying that elasticities of demand for outputs (supplies of inputs) are "blown up" by a factor  $1/\beta > 1$ . Under this modification, and ignoring momentarily the second discrepancy (2), the public firm would behave as a profit maximizer who overestimates the elasticities by a constant factor of proportionality  $1/\beta$ . It would thus levy tolls geared to demand (supply) elasticities—but to a lesser degree than would a monopolist. The rationale for taking elasticities into account<sup>109</sup> would seem to be that optimal tolls should be such as to equate the marginal losses of "surplus" to consumers *per dollar contributed to meet the budget constraint* (32) and not per dollar spent.<sup>110</sup>

As for the compensated nature of the demand (supply) functions, it is due to the fact that the approach of Boiteux consists in deriving *simultaneously* a set of tolls  $t_i$  (or shadow prices  $\pi_i$ ) *and a set of transfer payments*  $r^k$ ,<sup>111</sup> where the sum of the transfer payments is constrained by (31). (31) may also be written, in view of (32) as:

$$(31') \quad \sum_{k=1}^m r^k - \sum_{i=1}^n \sum_{k=1}^v p_i x_i^k = b$$

This formulation brings out more explicitly the fact that all profits (losses) of the public firm are automatically redistributed among the consumers. These income effects are thus taken into account. If rules of property income formation were specified for the consumers,<sup>112</sup> and the transfers disposed with, then the optimal tolls<sup>113</sup> would become simply proportional to the profit maximizing tolls—i.e., to the tolls that

<sup>108</sup> It can be shown that  $\beta$  would have to lie in that interval if  $b$  exceeds the profits to the public firm that would obtain under unconstrained Pareto optimality—i.e., if, for instance,  $b=0$  but the public firm operates under increasing returns.

<sup>109</sup> This was initially urged by Colson and later rejected by Allais, as mentioned above.

<sup>110</sup> That is, per dollar of net *marginal* and not average revenue.

<sup>111</sup> The rules governing the transfer payments are not stated by Boiteux. They can be derived, however, and have an interesting welfare interpretation.

<sup>112</sup> That is, rules of distribution among consumers of the profits of the business sector.

<sup>113</sup> They would, of course, no longer be given by conditions (33) but rather by a slight modification thereof.

would be charged by a private monopolist taking these property-income effects into consideration.

The previous paragraph brings out two important points. On the one hand, if the transfers (compensations) are *not* paid, then the tolls defined by (33) are no longer Pareto optimal. On the other hand, if the transfers are paid, then it is not necessary for the public firm to know what they are: all that matters is an estimate of the elasticities of the compensated demand (supply) functions. To that extent, decentralization of decisions is preserved.<sup>114</sup>

The extension to several public firms, subject to independent budget constraints, reveals first that the tolls levied on a given pair of goods or services must be in the same ratio for all firms; i.e., the toll structure of two firms are identical up to a proportionality constant.<sup>115</sup> The additional conditions, although they generalize quite naturally the single-firm conditions, are somewhat more intricate.<sup>116</sup>

To conclude, a major point of departure from previous solutions lies in the use of shadow prices for inputs as well as for outputs—hence in different factor proportions at all levels of output. This point had probably been overlooked because so much previous discussion centered around pricing problems for public monopolies that buy factors on competitive markets; it becomes vitally important in the case of a country like France where a nationalized electricity company buys coal from nationalized coal mines in order to produce electricity to sell to nationalized railroads. If a single budget constraint could be imposed upon the nationalized sector,<sup>117</sup> then the marginal cost of coal would be equal to its marginal productivity in electricity generation, when electricity is “priced” at a marginal cost equal to its marginal productivity for the railroads (e.g., in hauling coal!). With separate budget constraints, it would still be true that the marginal rate of transformation between coal and electricity would be the same in all three firms.

More broadly, the significance of Boiteux’s paper as a contribution to the theory of second best is worth stressing. The results surveyed here can be extended into a full interpretation of the constrained optimum position, including not only the transfer rules but also the specification of marginal social values for commodities and capacity in the public firm and an evaluation of the marginal social cost of the budget balanc-

<sup>114</sup> Yet, the actual tolls play a role in the determination of the transfers.

<sup>115</sup> The proportionality constants being such as to bring about budget balancing for each firm.

<sup>116</sup> In the interpretation of Boiteux, the tolls levied by a firm must now be proportional to the price differentials that would bring about differentials of the income-compensated demands (supplies) to the public *sector* proportional to the outputs (inputs) of *that firm*.

<sup>117</sup> Either explicitly, or implicitly, thanks to transfer payments between the nationalized firms.

ing constraint.<sup>118,119</sup> Furthermore, an interesting analogy between the problem treated here and an altogether different problem involving a budget balancing constraint suggests itself. One might indeed think of the two productive sectors as being not a private and a public one but rather a domestic and a foreign one. The budget balancing constraint imposed upon the public sector could then be reinterpreted as a condition of equilibrium on the balance of payment, and the tolls would provide a "scientific tariff." I have not attempted to compare Boiteux's results with those reached in the international trade literature—but will venture the guess that the attempt should prove rewarding.

### *Applications*

A systematic discussion of applications of the theory surveyed in this section to the management of French public utilities would be a paper in itself. The papers by T. Marshak [103] and J. R. Nelson [130] and Chapter X in J. Lesourne [81] provide such a discussion. I shall limit myself to a few general comments.

The principle of marginal cost pricing of a peak load was advocated by Allais [5] in connection with railroad passenger traffic—the objective being to depress and spread the peaks of national holidays. Yet to the best of my knowledge, no actual application to passenger traffic has ever been attempted. Instead, the main field of application of peak-load pricing has been electricity.

The determination of the marginal and expansion costs of production, transportation, and delivery of electricity, taking into account the geographical location and the daily and seasonal as well as random fluctuations of demand, is no easy task. It was successfully carried out at EDF on the basis of the original studies by Boiteux [27, 29], and according to principles of application developed by Boiteux and Stasi [39] for production and transportation, and by Bessière [25] for delivery.<sup>120</sup> In developing these principles, the authors assume that optimal production, investment, and transportation decisions result in (a) equality between short-term and expansion marginal costs, and (b) equality between marginal costs at all points upon correction for net transportation costs.<sup>121</sup>

The result has been a new tariff, known as the "green tariff"—which

<sup>118</sup> This fuller interpretation is veiled in Boiteux's formulations by the sign error and misleading normalization mentioned in footnote 101. Its development would deserve separate treatment.

<sup>119</sup> As was pointed out to me by L. Hurwicz, the analysis could profitably be extended to situations where the public sector does not buy or sell *all* the goods, but only a subset of them.

<sup>120</sup> I have expressed above, my reservations about the treatment of stochastic demand fluctuations in these applications.

<sup>121</sup> Net transportation costs are positive or negative depending upon the *actual* direction of transport.

is described and commented upon by Boiteux [34, 35] and Massé [111]. In most cases, its application results in three charges, the first a lump sum, the second proportional to electricity consumption, and the third a function (sometimes more, sometimes less than proportional) of the peak quantity for which delivery is guaranteed.<sup>122</sup> Three different combinations of the second and third charges are available.

By penalizing peak demands, this tariff has resulted in substantial reductions of the fixed investments of *Electricité de France*: Massé [111] estimates the reductions at 100 millions of dollars.<sup>123</sup> Optimal reaction to the tariff on the part of users has been studied by M. Algan and M. Simonard [2], who use a marginalist approach; this closes the circle!

In the field of transportation, important applications have also taken place. The theoretical studies on pricing under a budget constraint led the French railroads (SNCF) to revise some of their policies.<sup>124</sup> In a first stage (1947), rates and loading conditions were adjusted to the loadability of commodities, improving by 30 percent the average pay load per car and hence the competitiveness of the system.<sup>125</sup> More recently (1962), differentiation of rates according to marginal costs on each route has been introduced. Another major concern has been with the allocation of traffic between alternative means of transportation. An interesting example is discussed by P. Maillet [88].<sup>126</sup>

## II. Intertemporal Allocation

In 1947 Allais published a two-volume work, *Economie et intérêt*, in which he advocated several rather drastic policy measures: namely, a frozen wage rate for unskilled labor, a depreciating currency, 100 percent reserve requirements, and collective ownership of land—these being regarded as prerequisites for the success of further policies (such as compulsory retirement provisions) aimed at maintaining a zero rate of

<sup>122</sup> Three different combinations of the second and third charges are available. It is interesting to see that part of the fixed costs are absorbed by the second, not the third, element—cf. Bessière [25].

<sup>123</sup> As pointed out by Nelson [130], the financial implications of marginal cost pricing in France are blurred by the severe inflation experienced in the country. Although the tariff was designed so as to bring about budget-balancing, one really does not know whether this condition was actually met. What marginal cost pricing achieves, under constant returns to scale and inflation is, in principle, twofold: (1) by equating short-term and long-term marginal costs, it provides a revenue sufficient to cover the full costs of marginal investments; (2) by charging automatically to the consumers the exact differential in expenditure that displacements of demand would bring about, it protects the firm against a deterioration of its financial position due to shifts in demand. Cf. Boiteux [32, 34].

<sup>124</sup> See Hutter [71, 72, 73].

<sup>125</sup> This figure was quoted to me in private correspondence by R. Hutter.

<sup>126</sup> The valuation of human lives and of time, respectively, have been discussed by Abraham and Thédié [1] and Lesourne [83] in connection with road investments; a comparison of risks is given by Roy [151].

interest. The underlying justification was a set of optimality conditions for intertemporal allocation; these conditions were shown to call for a capital endowment identical to that which a competitive equilibrium with a zero rate of interest would bring about.<sup>127</sup>

Commenting fifteen years later upon this problem of an optimal capital endowment (capitalistic optimum), Allais [14] wrote:

For my part, I have met in this area two sorts of economists. For the first, the existence of a capitalistic optimum for a zero rate of interest is considered as a completely mistaken proposition; for the second, it appears as a commonplace truth, a sort of truism, that does not deserve any attention at all.

I would not be surprised if the first group consisted of economists denying any *empirical relevance* to the *criterion* of "optimal capital endowment," whereas members of the second group might be concerned only with the *price implications* of the criterion, not its relevance. I hope to show here that both views are simultaneously sound.

More recently, J. Desrousseaux [49] has defended the equally unconventional view that, even in a world of certainty, there should exist differences among the marginal productivities of capital reached in different industries. Again, the justification came from unconventional optimality conditions for intertemporal allocation. It will accordingly prove convenient to review from the standpoint of optimality criteria the contributions to the theory of intertemporal allocation due to Allais, Desrousseaux, and E. Malinvaud.<sup>128</sup>

### *Efficiency and Pareto Optimality*

Malinvaud [92]<sup>129</sup> studies *programs* extending over an infinite number of discrete time periods for an economy whose sets of production possibilities for each period are convex.<sup>130</sup> A program is a complete physical specification of the inputs, outputs, consumptions, and assets of all the decision units of the economy at all times. Two main criteria are used for comparing programs: namely, *efficiency* and *Pareto optimality*. Loosely speaking, a program is efficient if there is *no other feasible pro-*

<sup>127</sup> *Economie et intérêt* is a much broader study than this paragraph might suggest; it is indeed a systematic text on intertemporal allocation, investment and money that contains many original developments aside from those surveyed here.

<sup>128</sup> Interest in optimal capital endowments has more recently been revived in the United States, for instance, in connection with the "golden rule of accumulation" introduced by Phelps [145b] and with the work on turnpike theorems and optimal economic growth—see, e.g., Koopmans [75c]. No attempt will be made here to integrate the two bodies of literature. The informed reader will undoubtedly notice some striking similarities as well as the definite originality of the French contributions.

<sup>129</sup> This fundamental paper is discussed at some length by Koopmans [75], I.4.

<sup>130</sup> The technology may, of course, vary from period to period, as may the available natural resources and labor inputs.

gram<sup>131</sup> providing at least as much to consume of everything at all times and requiring no more labor of any kind at any time. As is well known,<sup>132</sup> this definition implies intertemporal conditions; efficiency within every time period is not a sufficient condition for intertemporal efficiency.

Pareto optimality of efficient programs is defined in the usual way, with reference to the infinite set of present *and future* consumers, whose preferences are taken as given. Thus, a program  $P_1$  is Pareto optimal if there is not other feasible program  $P_2$  such that  $P_2$  is strictly preferred to  $P_1$  by at least one individual whereas  $P_1$  is strictly preferred to  $P_2$  by no individual.

The criterion of efficiency refers only to the allocation of *given* resources in *production*. The criterion of Pareto optimality refers, in addition, to: (1) the allocation of resources (including labor services) between production and consumption; (2) the allocation of resources among individuals (born or unborn) and for every individual among time periods.<sup>133</sup> Again, intertemporal conditions are implied that go beyond those imposed by efficiency.

The price implications of efficiency and Pareto optimality, for infinite programs that satisfy a few rather weak conditions, have been stated by Malinvaud [92]. By a price system is meant a set of discounted prices (present values), one for each commodity in each time period.<sup>134</sup> The main price implications of efficiency are the following: (1) To every efficient program, there corresponds a price system<sup>135</sup> in terms of which the net value of the program is larger than or equal to the net value of any other feasible program that becomes *identical* with it beyond some *arbitrarily distant* time  $T$ ,<sup>136</sup> (2) The production plan assigned by the efficient program to every firm (production unit) has, in terms of the same price system, a net value larger than or equal to the net value of any other feasible plan for the same firm, given identity of the two plans

<sup>131</sup> "Feasibility" is relative not only to technology and natural resources but also to initial assets.

<sup>132</sup> See, e.g., Dorfman, Samuelson, and Solow [55], Chap. 12.

<sup>133</sup> Remember that a program specifies the consumptions and assets of all individuals at all times.

<sup>134</sup> If  $p_{it}$  is the present value of one unit of commodity  $i$  to be delivered at time  $t$ , then its undiscounted price at time  $t$ , say  $\tilde{p}_{it}$ , can be defined as  $\tilde{p}_{it} = p_{it}/\beta_t$ , where  $\beta_t$  is a proportionality factor independent of  $i$ ; ( $\beta_t$  may, for instance, be chosen so as to keep constant the undiscounted price of a *numéraire* commodity); the rate of interest at time  $t$  is then

$$r_t = \frac{\beta_t}{\beta_{t+1}} - 1.$$

<sup>135</sup> Possibly several price systems.

<sup>136</sup> By means of this device, Malinvaud has reduced the comparison problem to finite dimensionality. The awkwardness of comparisons among infinite programs is well illustrated by some recent work of Koopmans [75b].

beyond  $T$ .<sup>136a</sup> The price implications of Pareto optimality extend proposition (2) into the field of consumption: the consumption plan assigned by a Pareto-optimal (and hence efficient) program to every consumer has a smaller value than *any* preferred consumption plan that would become identical with it beyond  $T$ , in terms of the price system associated [by (1)] with the Pareto-optimal program. Conversely, if a program is efficient and such that for every consumer any preferred consumption plan would be more expensive (in terms of a price system associated [by (1)] with the efficient program), then that program is also Pareto optimal.

The proposition according to which *any* competitive equilibrium is (efficient and) Pareto optimal holds for intertemporal but finite programs. The extension to infinite programs involving an infinite number of individuals remains to be formulated.

### *Allais Optimality*

The relevance of Pareto optimality has been questioned on two grounds: (a) the preferences of unborn consumers must be taken into account; "... this implies in particular that a competitive economy will realize a Pareto optimum only if, among other conditions, the future consumers are already well represented on the market;"<sup>137</sup> (b) the preferences of consumers among present and future consumption may be biased.<sup>138</sup> An intermediate criterion, weaker than Pareto optimality but stronger than efficiency, that escapes these particular objections, has been suggested by Allais [6] and later referred to as the criterion of "Allais optimality."<sup>139</sup>

Although a rigorous statement of this criterion is quite involved,<sup>140</sup> an indirect statement may be suggested informally as follows: consider an *efficient* program and an associated price system  $p_u^*$ ,  $i = 1, \dots, n$ ,  $t = 1, \dots, T$ , where  $T$  is arbitrarily large; this efficient program is Allais optimal if there exists for each consumer  $k$  a set of coefficients  $\beta_{kt}^*$ ,  $t = 1, \dots, T$ , such that any preferred consumption program for consumer  $k$ <sup>141</sup> *would be more expensive at prices  $\beta_{kt}^* p_u^*$* . This should be equivalent to the statement that an efficient program  $P_1$  is Allais optimal if there exists no program  $P_2$ , such that (a) for all  $t = 1, \dots, T$ , the

<sup>136a</sup> The converse proposition, stating the efficiency of a program that meets conditions (1) and (2) for *some* price system, is considerably more intricate, due to the technical difficulty of ruling out indefinite storage of assets.

<sup>137</sup> Malinvaud [97], p. 147.

<sup>138</sup> Allais [6], p. 163, puts considerable emphasis on this second point.

<sup>139</sup> Malinvaud [97], p. 147.

<sup>140</sup> See Malinvaud [97], pp. 147-48.

<sup>141</sup> That again becomes identical beyond  $T$ .

aggregate value at prices  $p_u^*$  of the consumption of *every individual* during period  $t$  is the same under  $P_2$  as under  $P_1$ ,<sup>142</sup> (b) at least one individual strictly prefers  $P_2$  to  $P_1$ , but no individual strictly prefers  $P_1$  to  $P_2$ .<sup>143</sup> By contrast, Pareto optimality implies that there exists no program  $P_3$  such that (a') the aggregate value at prices  $p_u^*$  of the *consumption plan* (for  $t=1 \dots T$ ) of every individual is the same under  $P_3$  as under  $P_1$ ,<sup>144</sup> (b') at least one individual strictly prefers  $P_3$  to  $P_1$ , but no individual strictly prefers  $P_1$  to  $P_3$ .

The criterion introduced by Allais may have more intuitive appeal than the definition suggests. It amounts to accepting consumer preferences in the sphere of atemporal allocation, but not in the sphere of intertemporal allocation; this would be the case under a system of forced savings in an otherwise competitive economy. Accordingly, problems of intertemporal allocation become formally equivalent to distribution problems: the same consumer at different times is treated as several consumers, whose consumptions generate mutual "external economies," but among which transfers of income (resources) are regarded as interpersonal transfers.<sup>145</sup>

Allais optimality is, of course, a relatively weak criterion—it is much weaker than Pareto optimality, although definitely stronger than efficiency. The only question which its acceptability raises, in my opinion, is the following: if consumer preferences regarding the allocation of their consumption between this and the next period are not taken into account, why should their current preferences regarding the allocation of next period's consumption among individual items be respected?<sup>146</sup> If

<sup>142</sup> Thus, if individual  $k$  consumes under program  $P_i$  a quantity  $q_i^k(P_i)$  of good  $i$  at time  $t$ , the condition (a) is that

$$\sum_i p_{it} q_{it}^k(P_i)$$

should be the same, for all  $k$  and all  $t=1 \dots T$ , under  $P_2$  as under  $P_1$ .

<sup>143</sup> See Allais [6], pp. 165–66. It should be obvious that Pareto optimality is a special case of Allais optimality, with  $\beta^k_{kt}=1$ .

<sup>144</sup> Thus, (a') requires that

$$\sum_{t=1}^T \sum_i p_{it} q_{it}^k(P_i)$$

be the same, for all  $k$ , under  $P_3$  as under  $P_2$ .

<sup>145</sup> By contrast, much recent work on intertemporal allocation has been conducted in terms of aggregate consumption per period—thus disregarding the very intertemporal complementarities taken into account by Allais optimality, but stressing the allocation over time of an individual's aggregate consumption, which Allais optimality treats as a distribution problem.

<sup>146</sup> Again, why should the preferences of unborn consumers be better known in the second case than in the first?

consumers are apt to regret tomorrow the amount of today's savings, they are equally apt to regret today's commitment to more bread and less wine tomorrow.<sup>147</sup>

### *Stationary Programs and Optimal Capital Endowments*

The additional criteria used by Allais and (following him) Desrousseaux are more conveniently introduced if some properties of *stationary* programs are stated first. Assuming the self-renewing natural resources and labor services to be available at a constant rate of flow and the production possibilities sets of all periods to be identical, stationary programs are easily defined by the condition that economic activity remains unchanged from one period to another.<sup>148</sup>

As shown by Malinvaud [92], efficiency of a stationary program implies the existence of a *stable* price system and a *constant* rate of interest in terms of which net profits<sup>149</sup> are maximum for every firm. That rate of interest is equal to the marginal productivity of capital.<sup>150</sup>

In a stationary program, the quantity of every commodity carried over from one period to the next is the same at all times. Calling "capital endowment" a (stationary) vector of such quantities, we may now define an *optimal capital endowment* by a natural extension of the efficiency concept, namely:<sup>151</sup> an *efficient stationary* program is associated with an optimal capital endowment if it is efficient compared with all other stationary programs, whatever their capital endowment may be, but otherwise feasible, i.e., compared with all other "technologically feasible" programs.<sup>152</sup> Thus, if the capital endowment of a stationary program is not optimal, there exist additions to or *subtractions from* that capital endowment which would permit *permanent* increases of at least one consumption.<sup>153</sup> One may wonder why subtractions are mentioned in this connection. The reason is that in a stationary program the initial capital endowment must be *maintained forever*: no "capital con-

<sup>147</sup> The commitment is made irreversible at the aggregate level, by the investment decisions embodied in a program.

<sup>148</sup> Hence all stocks and flows are constant in time.

<sup>149</sup> That is, the discounted value of outputs minus the current value of inputs, which is the same for all periods.

<sup>150</sup> This is strictly true only under an appropriate continuity assumption; in general, the rate of interest is at least (most) equal to the marginal productivity of a positive (negative) investment.

<sup>151</sup> Malinvaud [92], p. 262.

<sup>152</sup> Thus there is no other stationary program—whatever its capital endowment may be—that provides at least as much to consume of everything at all times and requires no more labor of any kind at any time, within the assumed technology. The extension of the efficiency concept thus consists in relaxing the feasibility constraints, insofar as they reflect availability of initial assets—while imposing stationarity.

<sup>153</sup> Alternatively, permanent reductions of at least one labor input.

sumption" is permitted.<sup>154</sup> If too much capital has accumulated, relative to the available natural resource and labor services, the required provision for capital maintenance and replacement may imply a reduction in consumption or an increase in labor inputs.

It should therefore be no surprise that an optimal capital endowment, if it exists, implies a rate of interest and a marginal productivity of capital both equal to zero.<sup>155</sup> Indeed, in such a situation, an addition to the capital endowment could not result in any increment in consumption, the gross increase in production being at best exactly sufficient to provide for capital maintenance and replacement.

Whether or not *finite* optimal capital endowments exist is an open question—everything depends upon the available technology.<sup>156</sup> Necessary and sufficient conditions for capital to become a free good<sup>157</sup> have not been investigated yet, to the best of my knowledge.

### *Proportional Programs*

Can optimal capital endowments be defined for non-stationary programs? Yes—provided some condition is introduced to prevent capital consumption. Thus, *proportional programs* are defined by the condition that all stocks and flows should grow at the same rate, usually called *expansion rate* (a function of time). When all the primary factors (i.e., the self-renewing natural resources and labor) grow proportionately at some rate, then a proportional program is the most natural extension of the stationarity concept. This permits the following definition: an *efficient proportional program*<sup>158</sup> is associated with an optimal capital endowment if it is efficient compared with all other *technologically feasible* proportional programs<sup>159</sup> (whatever their capital endowment may be).

Programs of proportional *exponential* growth have been studied closely for linear models (characterized by constant returns to scale), such as that of J. von Neumann [168] or W. Leontief [79].<sup>160,161</sup> The relations between the expansion rate and the interest rate in a von

<sup>154</sup> If capital consumption were permissible, a state of satiation should be reached in order for additional capital to be worthless.

<sup>155</sup> Allais [6], p. 184; Malinvaud [92], lemma 8.

<sup>156</sup> See the comments by Koopmans [75], pp. 122 ff; Allais [6], pp. 196 ff. asserts that finite capital endowments exist for economies characterized by currently available technologies.

<sup>157</sup> In the sense of a zero price (marginal productivity) of capital; as pointed out in footnote 154, this does not mean satiation of wants.

<sup>158</sup> It is well known that a proportional program for which the rate of growth is maximal (in some sense) is not necessarily efficient; see Malinvaud [96].

<sup>159</sup> That is, compared with all other programs, whatever their capital endowment may be, but otherwise feasible.

<sup>160</sup> An interesting approach to the optimal equipment problem in a dynamic Leontief model has been developed by Faiveley [57b]; see also the summary by Massé [112], Chap. IX.

<sup>161</sup> The "golden rule path" of Phelps [145b] also falls in this category.

Neumann model have been investigated by Malinvaud [96], who shows that the rate of interest exceeds the expansion rate when consumption exceeds the inputs of primary factors. The converse proposition could be interpreted to mean that when the marginal productivity of capital (interest rate) is less than the expansion rate, the proportional growth of capital must be partly supported by reducing consumption (below the inputs of primary factors). Although Malinvaud does not address himself to that question, one would be tempted to conclude that if an efficient proportional program of exponential growth with optimal capital endowment exists, it must imply a rate of interest and marginal productivity of capital equal to the expansion rate.<sup>162</sup> This is a very reasonable proposition, considering that the *marginal productivity of capital is also the maximal rate at which growth of a marginal unit of capital can be self-sustaining (self-financing) in the absence of interest charges*. In other words, if interest charges are replaced by a growth condition on the initial endowment, the rate of growth plays a role analogous to the rate of interest—at least under constant returns to scale. Such would also seem to be the most natural interpretation of a similar result recently announced by Allais [14].<sup>163</sup>

### *Stationary Marginal Modifications*

Desrousseaux [49]<sup>164</sup> has attacked a version of the general case by means of an additional criterion, called "regularity." In applying this criterion, Desrousseaux opens an avenue of generalization of the concept of optimality of capital endowment—a generalization that may, in fact, be restated without explicit reliance upon regularity.<sup>165</sup>

<sup>162</sup> Malinvaud [97], Chap. V, discusses further the relation between the rates of expansion and of interest, using an approach of Hicks' [67b]. An unpublished paper by Malinvaud, "On the Rate of Interest of Efficient Proportional Growth Programs," Berkeley, 1961, should also prove relevant to the optimal capital endowment problem.

<sup>163</sup> That paper explicitly assumes exponential proportional growth of the primary factors but does not explicitly restrict attention to proportional programs; neither are returns to scale assumed constant; the paper is in the nature of an abstract, so it is hard to understand fully the implications of the announced results; Allais [14], p. 727, refers to a forthcoming book on these matters.

<sup>164</sup> The analysis of Desrousseaux is further developed in several stimulating unpublished monographs ("Caractéristiques globales des économies quelconques et taux d'intérêt optimal dans les mondes évolutifs," May, 1961; "Productivité des investissements et taux d'intérêt différenciés," March, 1962; "Réflexions sur la théorie de l'évolution économique, ses hypothèses, ses concepts et ses conclusions," August, 1962), and the author has announced to me in private correspondence forthcoming additional results.

<sup>165</sup> Applied to a single economic parameter, the criterion of regularity calls for minimizing the absolute value of the time derivative of that parameter. The idea is, of course, to rule out fluctuations, and one may regard the work of Desrousseaux as a step in the direction of a *joint* analysis of growth and fluctuations. Desrousseaux [50] offers an interesting discussion of the role of indivisible investments in the business cycle; some comments on the dynamic instabilities of a competitive economy are also given in [49] as well as in the unpublished monograph, "Réflexions sur la théorie de l'évolution économique," mentioned in footnote 164.

Following Allais [6, 14], Desrousseaux relies upon the Jevonian and Austrian concepts of a "characteristic curve" and of average periods of production and amortization for a capitalistic production process.<sup>166</sup> The simplest model is one in which there is a single primary factor, labor; labor can be used in alternative production processes that "mature" (i.e., result in consumption) after different periods of time. Capital is accumulated by shifting labor from processes with shorter periods of maturation to processes with longer periods, thus lengthening the average period of production. If a production process is defined by its maturation period, and if the level at which that process is operated is measured by the required labor input, then a function specifying the *distribution of labor inputs by maturation periods* gives a summary description of economic activity at a given time. When labor inputs at time  $t$  are expressed as ratios to aggregate labor inputs at that time, the corresponding function will be called "distribution function" for  $t$ .

For an economy with *given* aggregate labor inputs at all times,<sup>167</sup> the condition that the distribution function be independent of time (stationary) may be regarded as a condition of proportional growth.<sup>168</sup> Efficiency of a *stationary* distribution function is then defined by the property that no other distribution function (applied *indefinitely in the past* as well as in the future!) would permit more consumption at some time and at least as much consumption at all times. This property, because it applies to the past as well as to the future, has been regarded as equivalent to optimality of the capital endowment.

Desrousseaux [49, paragraph 234] shows that, if *efficient stationary* distribution functions exist, they imply equality at all times between the rate of interest and the rate of growth of the primary factor (labor), the latter rate being, of course, a function of time. Furthermore, Desrousseaux considers the class of programs for which any *stationary marginal modification* of the distribution functions (themselves no longer assumed stationary) would be inefficient.<sup>169</sup> By this is meant the following: given a set of distribution functions for all times (past and present), there is no other set of distribution functions, differing *infinitesimally*

<sup>166</sup> The reader who is unfamiliar with these concepts may find the following few paragraphs rather obscure. The best I can do is to refer him to Allais [6] for a systematic exposition. See also the comments on that approach by Malinvaud [92], historical note, and [97], *in fine*.

<sup>167</sup> That labor inputs are given does not mean that they are constant, or even growing at a constant rate.

<sup>168</sup> It will be noticed, however, that although all production processes are operated at levels proportional to aggregate labor inputs, the same proportionality does not hold for consumption and assets unless labor services grow at an exponential rate; this is so because consumption and assets are by definition proportional to a weighted average of past labor inputs; this is one of the troublesome peculiarities of the model under discussion.

<sup>169</sup> Desrousseaux is led to consider such programs by imposing the condition of regularity upon the *relative* labor inputs in every production process; my understanding is that the condition *actually* used is regularity of rates of change of the relative inputs; this distinction is immaterial from the standpoint of the results mentioned in the text.

from the former in a *stationary* way (by the same infinitesimal amounts at all times), and defining a program with respect to which the former is not efficient. If programs that are efficient with respect to such stationary modifications exist, they again imply equality at all times between the rate of interest and the rate of growth of the primary factor.<sup>170</sup>

As the example in the last paragraph shows, the concept of "optimality of capital endowment" can be extended to non-proportional programs by considering *constrained* marginal additions to the capital endowment—the constraints coming in to prevent capital consumption. (The constraints would thus bear upon replacement and growth of the marginal addition to the capital endowment.) The criterion of optimality of that capital endowment could then be stated (conditionally upon specific constraints) as follows: an efficient program is associated *at all times* with an optimal capital endowment if there is no marginal addition to (or subtraction from) that capital endowment at any time that would permit at least as much consumption of everything at all times and more of something at some time, *under the constraints imposed upon replacement and growth of the additional capital*. Thus the choice of constraints *defines* the criterion of optimality of capital endowment!

Precisely what constraints could be used meaningfully is an open question. If the condition were imposed that the additional capital should grow at a rate equal (at all times, or on the average) to the marginal productivity of the existing capital, then the existing capital endowment (whatever it may be) would automatically be found optimal under quite general conditions. Allais and Desrousseaux use a condition of growth (of a marginal addition to capital) at the same rate as the exogenous primary factor. (When that primary factor is labor, the marginal additions to capital result in a constant addition to capital per worker.) The optimality of such a criterion is by no means evident. If several primary factors were growing at different rates, the criterion would become ambiguous.<sup>171</sup> This difficulty is akin to that encountered if a criterion of maximum growth were to be defined for nonproportional programs.<sup>172</sup>

<sup>170</sup> This is my interpretation of the results reached by Desrousseaux [49], paragraphs 232–233. The concepts used by Desrousseaux require very careful handling and my interpretation may be incorrect. The correspondence between the models of Allais and Desrousseaux and the more familiar model of Malinvaud has never been systematically explored, to the best of my knowledge. Pending such clarification, it is hard to tell just how general is the result mentioned in the text.

<sup>171</sup> The solution chosen by Desrousseaux, namely, to impose different rates of growth for different capital goods, depending upon the rates of growth of the primary factors to which they are related, is definitely unconvincing. By anticipation of the next section, it may be pointed out that such a criterion would generally be inconsistent with Allais optimality and eventually even with efficiency.

<sup>172</sup> See Malinvaud [97], p. 149.

*Relevance and Compatibility of the Criteria*

As indicated above, Pareto optimality implies Allais optimality, which in turn implies efficiency, and optimality of capital endowment implies efficiency. So much is clear. Is there more to say?

Let us first remark that Pareto or Allais optimality clearly define policy-oriented criteria, whereas optimality of capital endowment (no matter how defined) depends *at a given time* upon *past* accumulation and is thus, *as of that time*, a matter of fact and not of policy. The first use to which the criterion could be put is thus evaluation of the available capital equipment. If one wished to go beyond this, for instance, to advocate policy measures aimed at accumulating an optimal capital endowment (as defined by appropriate constraints on capital consumption), the consistency of such policies with the criteria of Pareto and Allais optimality would have to be considered. For a class of Pareto optimal programs, namely, those implying a distribution of resources among consumers regarded as socially acceptable, it will typically happen that the class contains no program conducive to what has been independently called an optimal capital endowment. The class of Pareto optimal programs could conceivably be enlarged to a corresponding class of Allais optimal programs, namely, programs implying similar distributions of overall resources among consumers but less preferred intertemporal allocation of these resources by at least some consumers. This broader class might well contain programs that are conducive to an optimal capital endowment at some time or another (existence theorems in this area would be welcome). Allais' policy recommendation is that some such program (e.g., a program leading to the desired optimal capital endowment after 20 years) be adopted and the implied intertemporal allocation imposed upon consumers. But to say that consumer preferences for intertemporal allocation may be ill-defined or biased is not to say that *any* intertemporal allocation is as good as *any* other. Again, a socially acceptable subclass should be defined—and the question raised whether it contains programs conducive to an optimal capital endowment. However, by this time, social preferences among different intertemporal allocations for individual consumers are introduced. I think that the criterion of optimality of capital endowment could be treated similarly: the constraints entering its definition could be regarded as the expression of similar social preferences. It is my conjecture that the *concept* of optimality of capital endowment would then become redundant—but might (have) serve(d) a useful technical role in clarifying the technical implications of alternative social preferences for intertemporal allocation.<sup>173</sup>

<sup>173</sup> The foregoing is an attempt to assess the potential usefulness of the criteria of Allais optimality and optimality of the capital endowment in the hypothesis of meaningful social preferences among different intertemporal allocations for individual consumers. The para-

### III. National Planning

#### *What is French Planning?*

French planning has frequently been described as being "indicative."<sup>174</sup> In his preface to Perroux's recent book on the fourth plan [144], Massé, who is currently serving as *Commissaire Général au Plan*, specifies further: "... French planning is not imperative, but more than indicative; *active planning* would be more to the point; for it implies the initiation, within the general framework of the plan, of a string of special actions aimed at making the plan effective."

This concept of "active planning" is definitely intriguing for a foreigner like myself, who reads that a French four-year plan is a *law* (hence should be enforceable), but a law that defines the plan itself as being merely "a *framework* for the investment programs" and "a *guide* for economic development and social progress." That "law" is generally said to have worked well, although statements to that effect are almost never backed by conclusive empirical tests.

In very broad terms, the plan is a summary description of the (market) economy projected four years into the future and accompanied by a set of commentaries and recommendations. As such, it may be regarded as a giant marketing study at the national level. Because it is conducted at the national level, it may take into account macro-economic equilibrium relations (between saving and investment, imports and exports, . . . ), but it must also remain fairly aggregative. The prospective aggregate accounts, as well as the recommendations, provide a frame of reference for the decisions to be taken over that period by the government, by firms, and by individuals. The idea behind *indicative* planning is that such a frame of reference is indispensable for many decisions, and something may be gained by having as many decisions as possible taken within the *same* frame of reference.<sup>175</sup> The idea behind *active* planning is to associate many decision makers with the preparation and revisions of the projection. It is thus *hoped* that the projection, to the extent that it *forecasts and influences* their decisions, brings about enough consistency among decentralized plans and consensus among decentralized objectives to become substantially *self-realizing*.

Of course, planning concepts, methods, and instruments have evolved over the fifteen years since Jean Monnet, the father of French planning,

graph should not be understood as an advocacy of such a scheme by the present writer, who yet fails to be convinced of its merits.

<sup>174</sup> Just what is meant by "indicative planning" is not altogether clear; the term is often used as a shortcut for the description of French planning—a tradition which I shall follow here.

<sup>175</sup> That something may also be lost, should the "frame of reference" be erroneous, is obvious; an empirical analysis of the consequences of forecasting errors by the coal and steel community should prove instructive.

directed the preparation of the first plan. The major evolution came from the economic conditions to which the general objectives of the successive plans were geared.<sup>176</sup>

The *first plan* (1947–1952/53) aimed at speeding reconstruction and eliminating bottlenecks in the postwar economy by assigning priority to the expansion of six basic industries: coal and electricity, steel and cement, transportation and farm machinery (to which oil and nitrates were added as the period of the plan was extended into 1953). The achievement of the objectives was made easier by Marshall aid.

The *second plan* (1954–1957) was concerned with spreading development and progress throughout the economy (including agriculture). The emphasis was shifted from capacity toward productivity, with due attention to scientific research, personnel training, and the like. These objectives were attained and in many cases exceeded, but at the cost of inflation and balance of payments disequilibrium.

The *third plan* (1958–1961) had to cope with the above difficulties as well as with the 1957–58 recession. By taking monetary and international<sup>177</sup> problems into account, as well as by its ambitious production and investment objectives,<sup>178</sup> the third plan had a definitely broader scope than its predecessors.

The *fourth plan* (1962–1965) innovates further by treating explicitly the income distribution problem (with particular attention for the underprivileged and the choice between work and leisure), as well as by the priority given to social forms of investment—education, health, cultural, and urban equipment. Regional development is also included.<sup>179</sup>

If the differences in emphasis reflect the evolution of economic conditions, the progressively more comprehensive and ambitious objectives of the plans reflect partly the improvement of the tools and techniques used, partly the underlying transformations of the “economic order” and growing moral authority of the *Commissariat au Plan*. During the same time, the administrative organization and staff have not changed much, and the number and scope of instruments of authoritative implementation have gone down.

A brief description of the techniques, organization, and instruments of the plan is given under the next headings, introducing some comments about current orientations.<sup>180</sup>

<sup>176</sup> See, e.g., Bauchet [21], pp. 61 ff; Massé [115], II; Perroux [144], Introduction.

<sup>177</sup> 1958 is also the year during which the European Common Market was established.

<sup>178</sup> They were realized only for the revised second half of the plan.

<sup>179</sup> Regional economics has been a field of intense activity in postwar France; Boudeville [40, 41], Gendarme [63], and Perroux [134] are typical references to a literature that is constantly growing.

<sup>180</sup> A comparison of the French approach with that used in other Western European countries, like Italy or the Netherlands, would be very helpful—but goes beyond the scope of this survey; see Wellisz [169].

### *Tools and Techniques*

National accounts provide most of the basic data that are used for the preparation and revision of the plans.

Although it was invented in France with the *Tableau Economique* of François Quesnay, national accounting was almost nonexistent there before the war. The merit of its development into an important, and in many ways original, construction goes to another graduate of the *Ecole Polytechnique*, Claude Gruson, who created the *Service des Etudes Economiques et Financières* (SEEF) in the Ministry of Finance and was remarkably successful in making efficient use of rather scarce means.

The development of national accounts in France has been unusual in at least two respects. On the one hand, the technical and frequently arid nature of the subject did not deter a large group of first-rate economists from taking interest in it and writing about it.<sup>181</sup> Suggestions and criticisms have thus come from many directions, while information about the new tool and its possibilities became widespread. On the other hand, Gruson, himself an excellent theoretician,<sup>182</sup> was able to secure the collaboration of exceptionally capable analysts who contributed to the clarity of the system and the originality of its applications.<sup>183</sup> The two most outstanding instances, in terms of both the quality of their analytical work and the continuity of their association with SEEF, are André Nataf<sup>184</sup> and Pierre Thionet.<sup>185</sup>

While national income statistics are gathered by SEEF and the National Statistical Bureau,<sup>186</sup> money flows,<sup>187</sup> input-output tables,<sup>188</sup> and

<sup>181</sup> Some basic references are Allais [9], Gruson [66], Maillet [86], Malinvaud [95], Jean Marchal [100, 101], Perroux [133], Perroux, Uri and Marczewski [145], Prou [148]; the last reference contains historical notes; most of these contributions go beyond exposition or discussion of accounting techniques to build a bridge between national accounts and economic analysis.

<sup>182</sup> Witness [65].

<sup>183</sup> Thus, a yearly publication of SEEF, *Etudes de Comptabilité Nationale* [153], contains sometimes brilliant theoretical contributions, e.g., Thionet [162], Fourgeaud [59].

<sup>184</sup> Nataf has made very significant contributions to the theory of aggregation. See [125, 126, 127, 128] and [60]. Other major French contributions to the theory of aggregation are due to Guilbaud [67], Malinvaud [93, 94] and Thionet [158, 161].

<sup>185</sup> Thionet has written extensively on sample surveys and sampling theory—see, for instance, [157, 159, 163]—as well as on economic subjects.

<sup>186</sup> Institut National de la Statistique et des Etudes Economiques—INSEE.

<sup>187</sup> The French tables of money flows register, for some 40 types of monetary assets, the changes in the balance sheet (assets and liabilities) of the treasury, banking system, financial intermediaries, local administrations, households, business firms, overseas territories, and the rest of the world; for a detailed description, see Barthélémy [19].

<sup>188</sup> In 1951 two rectangular matrices were set up in terms of 112 "industries" and 157 "commodities," with consolidations into 37 industries and 65 commodities, and again into 12 industries and 12 commodities; one matrix gave a breakdown of the inputs of each industry into groups of commodities, the other a similar breakdown for outputs; in 1956, a classical square input-output matrix (with 66 sectors and a consolidation into 16 sectors) was

"economic budgets" are assembled at SEEF. Economic budgets<sup>189</sup> are prospective national income accounts serving as a framework for the treasury's budget and as a step in the preparation and revision of the plans. Furthermore, budget studies are carried out by a separate institution<sup>190</sup> in close cooperation with SEEF and INSEE.<sup>191</sup>

In very broad outline, these sources of information are utilized in the following way:<sup>192</sup> given a hypothesis about its rate of growth,<sup>193</sup> a projection of GNP is computed for the terminal year of the plan. Comparing this figure with the labor force forecast gives an indication of productivity changes which, in turn, serve as a basis for estimating investment requirements.<sup>194</sup> Subtracting these and prospective public expenditures<sup>195</sup> from the GNP figure yields aggregate consumption as a residual. Aggregate consumption expenditures are then broken down into commodity groups, on the basis of income elasticities (corrected for trends, demographic evolution, income redistribution, etc.). This step, together with an autonomous breakdown of public expenditures and investment, leads to a vector of final demands. A prospective input-output matrix (with coefficients adjusted for technical progress) is then called upon to translate final demands into gross output and employment figures for industrial sectors. The whole analysis is carried out at constant prices.<sup>196</sup>

Needless to say, the actual computations are much more elaborate than this outline reveals. Yet many subjective elements enter into the procedure: the figures for public and private consumption, the investment requirements and the technical coefficients are adjusted at various stages in the process of making the plan. The originality of French planning consists precisely in associating a large number of qualified and concerned outsiders with the preparation of the plan, through in-

used; for more details see, e.g., Mailliet [87, 89]. Regional input-output matrices have also been set-up, starting with Bauchet [20].

<sup>191</sup> Among independent studies providing or analyzing quantitative information in related areas, a special mention should be made of (1) the attempt by Divisia, Dupin and Roy [54] to evaluate national wealth; (2) the work of Fourastié [58] on prices and productivity; and (3) the work of Jean Marchal and his associates on distribution of the national income, Marchal and Lecaillon [102], Latil [78], Tavitian [155], Tiano [165], etc.

<sup>192</sup> For further details, see Gruson [66], Bauchet [21], pp. 149-160, or Betout-Mossé [26]. Paelinck and Wallbroeck [131] describe the closely parallel techniques used in Belgium.

<sup>193</sup> The role of such hypotheses is further discussed below.

stitutions shortly to be described. The presence of so many subjective adjustments deprives the projection of built-in consistency. This gives autonomous significance to the final consistency tests bearing upon employment and productivity, savings and investments, etc. . . .<sup>197</sup> Such tests are followed by further adjustments. How well alternative hypotheses regarding the rate of growth of GNP meet these tests is an important element of appreciation.

All told, the projection remains very coarse in several respects: it describes a terminal equilibrium, without consideration for the path by which it is to be reached or for the broad orientation of future plans; it runs in terms of highly aggregated sectors and of aggregate consistency tests (equilibrium is only roughly studied for regional employment markets, or for specific monetary markets); very few alternatives are explored.<sup>198</sup> Refinements are under way in most of these respects.

### *Men and Organization*

The French *Commissariat Général du Plan* is a relatively small administrative body with a total staff of some 100 employees and no official authority or financial means. It must rely upon outside administrative departments (such as INSEE and SEEF) for most of the data and studies required by its mission; thus, the regular government administration is automatically linked to the preparation of the plan.

Furthermore, the *Commissariat* is assisted by 25 *Commissions de Modernisation*, an original institution created by Monnet in order to turn the plan into a collective venture and to preclude bureaucratic sclerosis. Each commission consists of 30 to 50 appointed members, contributing their time without compensation and belonging mostly to three categories: public servants, business leaders, and labor leaders. Technicians, university professors, and representatives of other social groups join *study groups* into which the commissions divide to concentrate on particular problems.<sup>199</sup> Altogether, some 3,500 persons participate in the activities of the commissions and groups.

Of these 25 commissions, 20 are called "vertical" and each of these is responsible for a particular industrial sector (for example, iron and steel or chemistry) while five "horizontal" commissions, working across industries, are respectively concerned with labor, finances and general equilibrium, regional development, research, and productivity.

The work of the commissions in connection with the fourth plan (1962-1965) has progressed roughly as follows:<sup>200</sup> In June, 1960, each

<sup>197</sup> Additional tests involving prices are being developed and are discussed below—see footnote 219.

<sup>198</sup> These shortcomings are discussed at length by Perroux [144].

<sup>199</sup> A single commission may thus create up to 50 study groups.

<sup>200</sup> See Betout-Mossé [26].

vertical commission received from the *Commissariat* (1) *directions*, generally quantitative, regarding the rate of growth of GNP, the balance of payments, etc. . . . ; (2) *orientations*, of a more qualitative nature, regarding the development of social overhead capital, the length of the working week, and so on; (3) a *questionnaire* calling for the following data concerning the industrial sector(s) of the commission in 1965:

production and its uses (intermediate, final, outside . . . demand)  
 imports and exports  
 inputs from other sectors and sales to other sectors  
 investments, by types (plant, equipment . . . ) and source of financing  
 employment, by skills and by regions;

(4) past and *provisional accounts* for all industrial sectors—the past accounts coming from current statistics, the provisional accounts from preliminary theoretical calculations (of the type outlined above).

At this stage, about 250 industrial sectors were distinguished—to be consolidated later into 65, and finally, 28 aggregates. The commissions were expected, first of all, to examine past accounts, to reconcile them (if possible) with data supplied by their members (and originating in administrative departments, industrial and labor federations, business firms, and so on) and to suggest corrections if needed. This serves the double purpose of checking data currently used by the *Commissariat* and securing uniformity of concepts and definitions between the *Commissariat* and the commissions. Next, each commission was expected to fill the questionnaire with data again supplied (partly or wholly) by its members, working on the basis of the general directions and orientations mentioned above. How this can be done varies substantially from sector to sector. In those areas corresponding to activities of nationalized enterprises (power, transportation, public works), the forecasts and plans of the firms are directly used. In sectors where oligopoly situations prevail (e.g., automobile) much depends upon the willingness of the firms to disclose their plans and information. The experience seems to be that investment data are definitely easier to obtain than production estimates.<sup>201</sup> In competitive sectors (agriculture, manufacturing, services), statistical data and subjective evaluations by representative individuals (expected to consult with customers, suppliers, competitors) prevail. In all cases, the “provisional accounts” received from the *Commissariat* are supposed to be replaced by or amended through outside information.

At the same time, horizontal commissions received similar documents and performed a similar task. Employees of the *Commissariat* or collaborating departments (e.g., SEEF) check the work of the commissions,

<sup>201</sup> Perroux [144], p. 22, sees a danger in this collaboration of monopolistic firms in the plan: how could the planning authorities effectively curb monopoly power after that?

sometimes putting data into more appropriate form, sometimes supplying data not directly available to members, eliminating double counts or filling holes.

On this basis, a first synthesis was assembled by February, 1961, that was to serve a double role: (1) provisional revision of the central directives and orientations, in the light of the accounts supplied by the commissions; and (2) performance of consistency tests on these accounts (e.g., by comparing inputs and outputs as given by the buying and selling sectors or production figures as given by complementary sectors), and on their consolidation (investment, employment, GNP, foreign trade).

As the two sets of revisions are prepared by the *Commissariat* and the commissions (with growing importance attached to the horizontal commissions), a second synthesis emerges (May, 1961) upon consolidation of the 250 into 65 sectors and deeper examination of the macro-economic equilibrium relations. This calls both for statistical routine work and for arbitration of incompatibilities between the views of different commissions.

Once these data are regarded as final, they are aggregated again into 28 sectors and used to prepare the plan itself, with its commentaries and recommendations—an impressive document that was made available to congressmen in November, 1961. Although little room is left by then for modifications in the plan, attempts are currently under way to associate more closely the political authorities with the preparation of the plan by giving them responsibility for the early decisions about directions and general orientations.<sup>202</sup>

### *Instruments of Active Planning*

Once the plan has become a law, what instruments are at the disposal of the government in order to make it effective? In theory, there is a very simple answer to that question: no *special* means of economic control or rights of interference are attached to the existence of the *Commissariat au Plan* or the plan itself. Thus, only the ordinary tools of economic policy are available, and in France as in other Western countries, there are more carrots than sticks among these. Moreover, the plan is not really binding on the government and public services themselves, even when they are directly concerned.

However, in practice, it would seem that at least one important means of direct implementation has been effective and may be expected to remain so, namely, investment by the state and nationalized enterprises. In 1960 this accounted for 38 percent of metropolitan gross fixed

<sup>202</sup> See Massé [116].

investment.<sup>203</sup> If we add investments financed by public funds or by financial intermediaries subject to public control, each accounting for eight percent of the total, we see that *at least* 54 percent of total gross investment<sup>204</sup> was under public control. Since the Finance Minister has declared that the government was *in principle* under obligation to finance by priority the public investments called for by the plan,<sup>205</sup> at least that much is under control.

For the rest, it is through the usual decisions of economic policy that appropriate incentives or correctives can be created. In that connection, the main virtue of the plan is to provide a *consistent framework* within which these decisions can be taken. In many countries, such a framework is provided only by the yearly state budget, which is notoriously inappropriate.

Many of these incentives and correctives aim at influencing the decisions of business firms. The plan, however, is supposed to affect them directly in three ways:<sup>206</sup> by its influence upon their expectations; by the influence of public investment upon their demands and by the spontaneous adherence expected to result from participation in commissions and study groups. The first two points are obvious.<sup>207</sup> Few observers question their role in the recovery and rapid growth of the French economy since the war. As for the third point, although it is readily seen how it could be effective in isolated situations,<sup>208</sup> it has so far never been put to the hard test of facts: how effective this adherence would prove in cases of conflict between private interests and the orientations of the plan remains to be seen. Much would seem to depend on price and wage considerations, about which the plan has little to say so far.<sup>209</sup> The same reservations are in order in connection with the behavior of labor and consumers (savers). As more and more free wills and political interests are concerned, the prospects for "spontaneous co-

<sup>203</sup> According to figures reproduced by Bauchet [21b], p. 142.

<sup>204</sup> Indeed, financing by bonds is also subject to an element of control.

<sup>205</sup> Quoted by Perroux [144], p. 106.

<sup>206</sup> Massé [115], p. 14.

<sup>207</sup> The following personal memory, quoted by Massé [115], p. 6, in connection with the first plan, is a perfect illustration: "I remember the shock created at Electricité de France, where I had just been appointed Director of Equipment, by the target set at 39.5 billions Kwh, whereas prewar peak consumption was barely 21 billions. Without the coordinated effort announced by the plan, our skepticism would have rejected that ambitious goal." The target was accepted and nearly reached.

<sup>208</sup> Thus in location decisions, social welfare considerations (external economies and distributive effects) are likely to be more naturally taken into account by those who have been concerned with regional development aspects of the plan.

<sup>209</sup> Thus: would firms create the additional capacity called for by the plan, instead of striving for monopoly profits or in spite of pessimistic price expectations? I, for one, remain to be convinced.

operation" become dimmer. The emphasis by the fourth plan on income policy, in spite of its tentative nature, affords some ground for hope. Again, the desirability of empirical testing of the effectiveness of the plan should be emphasized.

### *Current Orientations*<sup>210</sup>

In several recent papers, Massé [113, 114, 115, 116] has exposed the conception underlying his current endeavors as *Commissaire Général au Plan*. Three major ideas are recurrent in these writings.

The first one is that French planning should remain indicative. Additional means of central direction and coercion are nowhere advocated. "Changing our policy with respect to means would foster neither human promotion nor, after all, efficiency."<sup>211</sup>

The second idea is that the plan is and should become more and more an *instrument of conscious social choice*. Massé takes at the same time a humble and ambitious view of his task when he writes:

Choice among ends is a political act that goes beyond . . . the programmer's task. The latter must, however, submit sufficiently clear, precise and timely alternatives for all democratic procedures to be open. Clear enough to be understandable by the common man. Precise enough for political decisions to escape ambiguity. Timely enough, so that these decisions do not entail reconsideration of practically completed plans.<sup>212</sup>

In this connection, Massé has stressed particularly choices between present and future consumption, between work and leisure, between goods of individual consumption and collective services, between individual freedom and economic benefits,<sup>213</sup> as well as the traditional problems of income distribution, full employment versus monetary stability, and so on. By exploring within a general equilibrium framework the economic implications of such choices and connecting them with specific policy measures, it is hoped that more conscious and more consistent choices may be made. If French planning proves successful in that respect, the achievement will be remarkable, and the consequences may be tremendous. A particular difficulty stems from uncertainty considerations. To choose between an immediate advantage, for example, increased consumption or faster growth, and an abstract, immaterial one, such as a higher (subjective) *probability* of maintaining balance of payments

<sup>210</sup> Perroux [141], I, describes a policy concerned with the real factors of growth and fluctuations of which active planning might be regarded as an instance. A more formal analysis, linking French planning to the decomposition algorithm of linear programming, has recently been presented in an unpublished monograph by Malinvaud [97b].

<sup>213</sup> In connection with labor mobility, for instance.

equilibrium, is not easy, and the temptation is great to give systematic preference to the former.<sup>214</sup> Massé's appealing approach to this problem is to develop alternative plans, all of which would satisfy the equilibrium constraints at the same probability level.<sup>215</sup>

Obviously, the procedure described in the preceding pages for preparing a plan cannot be used for exploring systematically many alternatives—hence the need to rely upon theoretical computations for the construction of such alternatives. This brings us to the third idea underlying Massé's recent writings, namely, that much remains to be gained, within the framework of indicative planning, by heavier reliance upon formal optimization models at the level of the *Commissariat*. It is certainly revealing that three of the four papers under discussion<sup>216</sup> start with a reference to the work done at EDF in connection with investment and pricing and its progressive development from marginal toward global, and from partial toward integrated approaches. The duality property associating a price system with the quantitative optimum and the equality there between short-term marginal costs and expansion costs<sup>217</sup> are repeatedly referred to,<sup>218</sup> and they obviously constitute, in Massé's opinion, important analytical tools of decentralized planning, so far unexploited.<sup>219</sup> Perhaps equally revealing are the references to the

. . . intellectual stimulation derived from programming efforts, and in particular, from the difficulties and possible failures of initial attempts. Literary reasoning admits of imprecisions and obscurities. Cal-

<sup>214</sup> Such also seems to have been the case in connection with the fourth plan; see Massé [115], p. 21.

<sup>215</sup> See Massé [114], Section V.

<sup>216</sup> That is, Massé [113, 114, 116].

<sup>217</sup> See pp. 9 and 10.

<sup>218</sup> Massé [114], p. 15 and [115], p. 14.

<sup>219</sup> The only systematic attempt at exploring the price implications of a plan is the suggestive model of Nataf and Thionet [164]. This "middle-term model with variable prices" may be described as a means of verifying the existence of a vector of *relative* prices compatible with (i) the quantitative projections embodied in the plan, (ii) a set of accounting identities to be verified for the terminal year in terms of these prices, and (iii) a set of relations expressing the monetary behavior of the government, firms and households—relations that are expressed (as a first approximation) independently of these relative prices. Thus:

(a) the price level is left unspecified—a useful limitation;

(b) price elasticities are completely ignored—a severe limitation! The structure of the model is the following: A set of accounting identities and behavior relations for each industrial sector is reduced to a system of equations (I) (one by sector) that are linear (but not homogeneous) in the prices (or rather price indices) of sectorial outputs, with coefficients involving the direct and indirect tax rates as well as behavior parameters. Similarly, accounting identities and behavior relations for the government, households, and the rest of the world are reduced to a system of inequalities (II), linear in the same prices, with coefficients involving the same tax rates as well as behavior parameters. Thus, to any set of tax rates and behavior parameters, there corresponds a unique set of relative prices by equations (I), and these

culatation, which forces searching of the shadow areas, leads to better and more clearly-expressed ideas, even when one finally comes back to literary exposition. . . . Furthermore, formal models have logical properties that can be used for exploration and consistency tests. . . .<sup>220</sup>

These properties of formal techniques should be used for technical sub-optimization with respect to such variables as choices of activities (domestic production versus imports), of investment programs (more or less capitalistic techniques for alternative sectors), of investment types (machines versus education), and so on.<sup>221</sup> They also seem to be the only currently available techniques by means of which some longer-range considerations could be brought to bear upon current plans.<sup>222</sup> Two special research bureaus, CERMAP and CEPREL,<sup>223</sup> respectively devoted to mathematical methods of planning and long-range forecasting, have recently been set up to provide the *Commissariat du Plan* with appropriate scientific support.

It is my conviction that important developments may be expected in the future: the significant contributions made to the management of public utilities will be extended to the level of national planning.<sup>224</sup> In this way, French planning might come one step closer to the normative economist's ideal: to combine efficiently the welfare properties of decentralized market mechanisms with conscious social choices about ends, informed evaluation of future events by men of judgment, and technical optimization of policy decisions by men of science.<sup>225</sup> As for the positive economist, he now is apt to regard current developments in France as

---

prices may or may not satisfy the inequalities (II), as well as general plausibility conditions (non-negativity, of course; dispersion of prices for close substitutes, etc.). If no satisfactory price vector exists, the tax rates and behavior parameters may be regarded as inconsistent.

One of the most crucial and least convincing relations of the model imposes *proportionality* between the gross investment of a sector, as given by the plan, and gross profits (the latter implying prices through the input-output relations, and affecting the government's tax receipts and the property income of households). While the behavior relations are rather rough, the accounting identities are sometimes luxurious; they entail projected money flows tables—see footnote 187 above. Serious analytical difficulties would, of course, be associated with explicit treatment of price elasticities; accordingly, numerical exploration of alternative parameter values is more fruitful at present. This might well be the type of model for which analogue computers would be ideally suited!

<sup>221</sup> See Massé [114], Section III.

<sup>222</sup> The experience at EDF in connection with long-range investment planning, and the advisability to push current research and experimentation with tidal and nuclear power, has revealed the usefulness of a linear programming approach to explore substitutions that a less integrated model could not reveal; see Massé [122], Ch. IV.

<sup>223</sup> CERMAP, *Centre de Recherches Mathématiques pour la Planification*, 19 rue de Passy, Paris 16, is headed by A. Nataf; CEPREL, *Centre d'Etude de la Prospection Economique à Moyen et Long Termes*, 16-18, rue Berthollet, Arcueil, is headed by J. Bénard.

<sup>224</sup> [97b] is a step in that direction.

<sup>225</sup> The hope that a more scientific approach to policy formation should prove helpful is, of course, basically an expression of confidence in the ability and objectivity of the people involved.

The dominating economic aim in Denmark in the postwar period has been to achieve both a high and rising level of economic activity and equilibrium in the balance of payments. In 1956 the ministry of finance, under a decision by parliament, established a commission on which served a number of economists in addition to representatives of labor organizations and several other pressure groups. This committee reviewed the situation, under its terms of reference, in order to ascertain to what extent recent economic difficulties were due to a lack of co-operation between public and private organizations and institutions which wield a major influence on economic development and to explore how improved cooperation might be secured in the future. Among the principal conclusions stated by the committee in its report were: (1) Denmark's failure since the early 1950's to achieve rapid economic growth was due in large part to stagnating foreign demand for agricultural exports and an unfavorable development in the terms of trade; and (2) The damage from these external factors had been intensified by the efforts of labor and other organized groups to increase their money incomes, resulting in a rising domestic cost level.<sup>1</sup>

### *I. Monetary Theory and the Problem of Inflation*

The above analysis was followed by a comprehensive study of price developments in relation to employment by E. Hoffmeyer in 1960 [13].

\*The author is professor of economics at the University of Aarhus, Denmark.

<sup>1</sup>The committee largely confined its analysis to developments in the postwar period and ignored the fact that at the beginning of that period the cost level in Denmark had increased appreciably in relation to most of its close competitors.

From a scrutiny of the historical record, and in particular of the post-war period, it was concluded that despite the close and quantitatively important interrelations of the Danish economy and the world market, price developments in Denmark normally cannot be explained as a direct consequence of international conditions which, although not without importance, must take second place in the analysis of the problem of inflation. Domestic price developments are viewed as the result of a struggle between employers and employees for larger shares in total income. The two principal preconditions that Hoffmeyer considers essential for a successful stabilization policy are: first, an understanding that the distribution of income is crucial in the problem of inflation and, second, an agreement between the major pressure groups concerning the distribution of income and the means to its implementation. In line with this basic view, relatively little attention is paid in the analysis to the repercussions peculiar to an open economy or indeed to the effects on employment and resource allocation of changes in wages or prices.

Diametrically opposed to this approach is the analysis of inflation [24] (1954) and general monetary theory [23] (1948) evolved by Jørgen Pedersen, who already played a leading role in the development of modern monetary and, in particular, fiscal theory [20] during the interwar period in Denmark. Fundamental to the analysis here is the proposition that in the circuit flow of income there is a basic difference between the position of, and the behavior patterns relating to, the contractually agreed income of wage earners on the one hand and the income of entrepreneurs on the other hand. As a residual magnitude, the latter cannot be directly determined by the recipients in a way analogous to that in which wages are agreed upon.

The general level of prices depends on three magnitudes: the level of wages, the marginal productivity of labor, and the degree of monopoly. The degree of monopoly depends in turn on institutional, psychological, and sociological factors. The marginal productivity of labor is governed by natural conditions, the stock of equipment, technical knowledge, and the level of employment. The level of wages remains then as the only purely monetary element among those factors which determine prices. Whereas a change in the distribution of income may be called forth by a change in the level of employment or in the degree of monopoly, the level of wages in a closed economy (assuming a completely elastic supply of credit) may be changed arbitrarily without any change in the level of employment or the allocation of resources. However, prices and residual incomes will increase or decrease in proportion to the change in wages. Essentially this analysis is based on a

fairly simple model where labor is the only variable factor of production and where, in consequence, the real wage rate is a—declining—function of the level of employment.

Apparently this analysis by Pedersen differs radically from that of Hoffmeyer (1960) [13]. After a detailed discussion of the cumulative effects of the automatic cost-of-living adjustments of wages in Denmark, Hoffmeyer concluded that following an initial increase in money wages the rate of induced price and wage increases will diminish rapidly, presumably with the implication that real wages will have increased. An analogous conclusion was reached by P. Norregaard Rasmussen in 1956 in discussing the effect on the price level of a rise in import prices on the basis of an input-output matrix with imports and labor as the only two primary factors [30]. In this instance the conclusion follows necessarily from the restrictive assumptions of the analysis. Whereas Hoffmeyer's analysis would appear simply to ignore repercussions between real wages and employment, the conclusion reached by Pedersen is explained by the different setting of the problem—the relationship between wages and prices at a constant level of employment and by the assumption that given the state of technical knowledge, the material means of production, the market structure, and so on, a definite functional relationship holds between the level of employment and the real wage rate. Under these assumptions the validity of Pedersen's conclusion is not confined to the case of a closed economy. In an open economy also, the level of money wages may be considered the only monetary element in the price system in the sense that under given conditions of technique, market structure, and so on, any change in the general level of wages must be accompanied by a proportional change in the price level—including the prices of foreign exchange—if the level of employment is to remain constant.

In conformity with this view, the equilibrium rate of exchange is defined as that rate which, in the absence of trade restrictions and at given employment levels, secures equilibrium in the balance of payments. If maintenance of a certain position of the balance of payments on current account is desired, rates of exchange will have to be adjusted in conformity with the changes in wages at home relative to wages abroad, insofar as such changes are not offset by changes in efficiency.

A natural consequence of Pedersen's theoretical model is the definition of inflation as a rise in wages, however brought about, provided that the banking system is willing to supply sufficient finance so that unemployment does not result.

Closely related to this definition is the view referred to above that

the respective roles played by wages and entrepreneurial income in the monetary system are fundamentally different. Elaborating this point Pedersen gives the following example. Suppose that in a country much dependent on foreign trade there is a great deterioration in the terms of trade or some other disturbance of the technical conditions of production, or that the employment of a rapidly growing population requires a great expansion of capital equipment leading to the development of so-called bottlenecks. In both cases there will be a rise in the level of prices which is technically, and not monetarily, caused, and which would lead to equilibrium if wages were kept constant [24, p. 71]. A crucial question here is whether an expansionary process that encounters a physical barrier due to a shortage of capital equipment while labor is still unemployed will automatically come to a halt and a new equilibrium be established if money wages do not rise. To establish the parallel to the normal case of inflation at full employment, the assumption must be of course that the prospective rate of profit has risen for some reason and that the supply of credit is elastic. As output rises and full capacity output is approached, prices will rise both absolutely and in relation to wages since the marginal productivity of labor falls. If unemployment is still considerable, wages may be assumed to remain constant. Since income is shifted from wages to profits, excess demand for commodities may be removed and equilibrium attained if the propensity to spend is lower for entrepreneurs than for wage earners (and *rentiers*). However, the rise in prices has raised the rate of profit and although the fall in wages in terms of commodities will induce a reduction in the capital intensity of new investment, the net effect may be that as prices rise total demand for consumption and investment will increase as fast as or faster than the value of total supply so that the gap between demand and supply is not closed.

Adopting the point of view that inflation should not be measured by commodity prices but by the price of labor, i.e. wages, Pedersen claims that: "it is obvious that the effect of the movement of wages on the behaviour of entrepreneurs is the same whether the rise in wages exceeds or falls short of the rise in effectivity." [24, p. 73]. However, this could hardly be correct; commodities can be stored, labor cannot. If wages after having been stable start rising by 4 per cent per year and in one case productivity is unchanged so that prices rise at the same rate, while in another case productivity also rises so that prices remain stable, entrepreneurs will in the first instance, but not in the second, be induced to accelerate purchases if the rate of interest is unchanged.

In line with contemporary theory, Pedersen defines the rate of interest as the price of money. Since the supply of money is ultimately

determined by the monetary authorities, the rate of interest becomes a policy parameter. In relation to the economic system, the rate of interest is, in other words, an exogenous magnitude depending upon the action of public authorities. It does not follow that the level of the rate of interest may be fixed completely arbitrarily without serious consequences. If the rate of interest is held below a certain level, the result will be uncontrolled inflation. If in contrast the rate of interest is raised above a certain level, economic activity will contract to a politically intolerable degree. The propensity to consume and the inducement to invest, which according to theories along classical lines determine the rate of interest, influence the position of the ceiling and the floor to the rate of interest as defined above. However, the decisive point is that the system contains no effective mechanism which automatically adjusts the rate of interest when either the propensity to consume or the inducement to invest changes.

It is difficult to judge whether there is a difference of principle or only of emphasis between this point of view and that presented by Hoffmeyer in 1958 [12]. After consideration of both historical evidence and of a Keynesian model, Hoffmeyer concludes that in the long run the rate of interest is determined by real economic conditions although in the short run the policies pursued by the monetary authorities may be of considerable importance.

Drawing in part on his own research, Pedersen [25] observes that the rate of interest charged for bank loans has little or no influence on the volume of bank credit. On the other hand, credit rationing by banks is deemed irrational from every point of view as causing great disturbance to the economy. It is not concluded from this that credit policy as an instrument for the control of economic activity should be abandoned. The demand for bank credit is largely a function of the rate of interest ruling in the capital market. The central bank may therefore control the demand for credit through open market operations. However, it is held that the central bank should make no attempt to correct temporary disturbances in economic activity or in the balance of payments, but should see its only objective in the long-run adjustment of investment demand to the resources available in a fairly fully employed economy.

Based largely on Pedersen's analysis, J. H. Gelting, in 1948 [6], discussed fiscal policy as an instrument for controlling the level of economic activity. Representing fiscal, credit and exchange rate policies by the three policy parameters: using  $t$  for level of taxation,  $i$  for interest rate, and  $v$  for the rate of exchange, the interrelations of the three branches of economic policy may be illustrated by the equations

( $F$  = foreign balance,  $K$  = capital exports, other symbols conventional):

$$(1) \quad Y = C(Y, t) + I(Y, i) + F(Y, v)$$

$$(2) \quad K(i) = F(Y, v)$$

Given the desired level of activity and thus of national income (at given constant wage rates), the above equilibrium conditions leave one degree of freedom in the choice of the values of policy parameters—any two may be represented as functions of the third. Based on Danish national income data for the interwar period, an attempt was made to ascertain (1) values of the marginal propensities to consume, invest, and import; and (2) the elasticity of investment with regard to the rate of interest for which a numerically high value of about two was found. These results were combined with a fairly detailed multiplier analysis in a discussion of the effects of alternative fiscal policies and the degree of built-in stability. As was usual in the Danish discussion of the early postwar period, much was made of the greater predictability of the effects of fiscal as compared with credit policy. The most important (or, at least, theoretically most interesting) argument was that the fundamental relation between the rate of interest and the desired stock of capital is of little help in predicting the effect of a *change* in the rate of interest on the *rate of change* of the stock, i.e. investment.

Observing that a number of propositions implied by the quantity theory of money would become less questionable if the word "income" was substituted for "money," Pedersen, in 1944 [22], suggested a corresponding terminological change. Earlier K. Philip [26] had made a highly original attempt to base the analysis of the activity effects of fiscal policy on the changes produced in the cash position of the private sector. Although this approach may have induced, to some extent, an underestimation of the differences between various types of fiscal intervention, it was not necessarily a consequence of the method adopted.

Recently, J. Vibe-Pedersen [32] (1961, 1962) contributed to monetary theory through detailed elaboration of the multiplier analysis. Preliminary to a comparison of the effects of direct and indirect taxes, he discusses the form of the consumption function and, in particular, the implications of the existence and non-existence of money illusion is discussed. The main analysis is based on a disaggregated model in which distinction is made between entrepreneur and wage earner households, investment and consumer goods production, and within the last sector between the production of material goods and services. An increased generality is imparted to the analysis by dropping the restric-

tive assumption of constant prices relative to wages. Thus, real and money income multipliers may be distinguished and the distributional effects of economic expansion are analyzed in terms of the two crucial elasticities of output in respect to employment and prices as related to output.

Pursuing disaggregation along rather different lines, I. Grünbaum [10] (1945) discussed the conditions of monetary equilibrium in terms of the *ex-ante*—*ex-post* analysis of the Swedish school. By showing that in spite of overall equality between *ex-ante* savings and investment, the coexistence of opposite discrepancies between demand and supply in the markets for goods and for factors (labor) might give rise to cumulative deviations from equilibrium, Grünbaum's paper proved fruitful by providing one of the leading ideas in Bent Hansen's "Theory of Inflation" [11] (1951). Although under normal conditions the coexistence of excess demand in the labor market and excess supply in the market for goods would appear highly improbable, this construction was presumably relevant to conditions in some western European countries, and in some of the less developed countries during the early postwar period.

A considerable number of both historical and theoretical studies of the Danish money and capital markets and their institutions have appeared since World War II, in particular "Bankerne og Samfundet" [34] (1955), T. Glud [8 and 9] (1951 and 1957), Hoffmeyer [14] (1960), E. Rasmussen [28] (1955), Uldall-Hansen [31] (1959), and P. Winding [33] (1958).

K. Bjerke and N. Ussing [1] made a study of the Danish national product 1870-1950. Methodological problems of the input-output analysis were discussed by Nørregaard Rasmussen [30] (1956). The input-output structure of the Danish economy in postwar years was investigated by Leo Meyer, Leif Heltberg, and O. Bak Olsen [18] (1962).

## II. *Theory of Wages*

In 1954, P. Milhøj [19] traced the development of wages in Denmark from 1914 to 1950, partly on the basis of previously unpublished material. An audacious attempt was made to construct a series of figures on the share of wages in national income on the basis of indices of wages and of total employment. Although the results may have a large margin of error due to the absence of systematic labor force statistics and of adequate wage statistics in Denmark, the movements in the share of wages in national income mostly conform to theoretical expectations. Rather surprisingly, however, it was found that during

the depression of the 1930's the share of wages in the national income declined substantially from 1930 to 1933. Part of the loss appeared to be restored in the following years despite the expansion of employment under difficult conditions, characterized by unfavourable terms of trade and a relatively lower foreign trade turnover than in the preceding decade. The implications for the distribution of real income in these rather uncertain movements in the share of wages were modified by the sharp fall from 1930 in the relative prices of food. During World War II, when employment increased strongly at the same time productivity was unfavourably affected by dwindling supplies of imports, the wage share declined to a minimum for the whole period. After the war, the wage share rapidly reattained the level of the late 1920's. Developments in more recent years are covered by Hoffmeyer [13]. It appears that the increase in the share of wages continued at a slow rate until the mid-1950's. For the period from the mid-twenties to the end of the 1950's, there was little over-all trend in the wage share. However, this stability was the net result of a pronounced decline in the share of wages in agricultural income due to the migration of workers out of agriculture as well as to a moderate increase in the share of wages in income produced by other industries. At least in the later part of the period, this rise did not reflect an increase in the share of production workers' wages but rather a relative rise in the number of administrative personnel.

Principal attention was given by P. Milhøj [19] (for the period of 1914-1950) to the evolution of wage structure, which among the organized trades shows a remarkable stability, although generally with a slight reduction in wage differentials between skilled and unskilled workers and between the different skilled trades. In covering the post-war period, A. H. Dahl [2] also finds a considerable stability in the industrial wage structure. Repeated attempts have been made to effect general wage agreements which would narrow differentials between skilled and unskilled workers. In addition the automatic cost of living adjustment of wages in Denmark tends to reduce wage differentials. Nonetheless, shortly after each new agreement, market forces, operating through wage drift, have largely re-established the previous wage structure and in the end have produced little change in relative wage differentials.

However, in certain sectors of the labor market previously characterized by relatively low wages and a low degree of organization, wages have increased strongly, resulting in a pronounced reduction of wage differentials. Most important among these is the field of agricultural wages. The fundamental analysis of this development was provided by

Pedersen in 1945 [21] in a discussion of the implications of full employment for the cost of living. A permanently higher level of employment outside agriculture would call forth a migration of workers from agriculture to other industries which would result in a narrowing of wage differentials and a consequent adjustment in the relative price of food.

The discussion of the evolution of wage structure has been closely connected with that of the extent and causation of wage drift, which has attracted interest mainly as a presumed major cause of Denmark's balance of payments difficulties. Pedersen, in his analysis of inflation, [24] makes a distinction between autonomous inflation due to the action of trade unions and induced wage increases caused by excess demand in the labor market—evidently a distinction corresponding quite closely to that between cost-push and demand-pull inflation. Investigating early postwar developments, A. Lund [16] found that the extent of wage drift varied with the level of employment and that, insôfar as the results of wage drift had not been codified in wage agreements, a subsequent decrease in employment might lead to a reduction of wages by removing wage increases over and above agreement rates.

In 1959, Dahl [2], who was interested mainly in the question of wage structure, viewed wage drift primarily as the way in which market forces, i.e. relative scarcities of different types of labor, corrected the wage structure established through wage agreements. Hoffmeyer [13] made an intensive investigation of the question of wage drift. Although it is not denied that the state of market demand is an important influence, other factors may be equally or even more important, such as the system of wage payment or the wage policy of the individual firm. As appears from a subsequent discussion (Gelting [7], Hoffmeyer [15]), these negative findings relating to the influence of demand are in large part to be explained by the fact that they are based on a period in which the level of unemployment in Denmark was comparatively high. If the period of observation had been extended to include subsequent years in which the level of employment rose appreciably, the influence of the state of market demand presumably would have been judged to be higher. It would appear then that the extent of wage drift is determined predominantly by the state of demand when, and only when, the level of unemployment is comparatively low—a conclusion which accords with the experience in other countries.

### III. *Farm Economics*

H. Gad [4] investigated the development of the agricultural labor force since the beginning of the 19th century. In a subsequent work

[5] a more detailed account is given of the changes in the size and structure of the Danish agricultural labor force and of the changes in agricultural wages from the middle of the 1930's. The movements in agricultural wages are explained by the decline in employment in agriculture, the increase in prices of farm products, changes in technical conditions inside agriculture, and developments in wages and employment outside agriculture.

Primary interest attaches to an audacious attempt to determine the demand curve for labor in Danish agriculture on the basis of farm accounts. The analysis covers six five-year periods from the middle of the 1920's to the middle of the 1950's. It was noted that on farms above 30 hectares the marginal input of labor is supplied by hired workers, whereas on smaller farms the entire or almost the entire labor input is supplied by the owner of the farm and his family. From these observations it was concluded that on the larger farms the farmer will attempt to adjust the input of labor in such a way that the marginal value-product of labor equals the money wage, whereas on the smaller farms the input of labor will be pushed to the point where the marginal value-product of labor is equal to the subjective supply price of the farmer, which may be lower than the market wage because of the absence of alternative income opportunities for the farmer. Typically the input of labor per hectare is much larger on the small farms than on the large farms. Thus, by comparing the economic results from large and small farms one might be able to determine the marginal productivity curve for labor.

However, for a number of reasons the author's interpretation of the results is open to doubt. First, the differences between small and large farms in the input of labor are accompanied by differences in the structure of output and, in particular, the input combinations of other factors of production. Therefore the differences in economic results between small and large farms cannot be claimed to reflect the marginal productivity of labor in the usual sense of this term. Secondly, the observed differences in economic results may reflect mainly returns to scale. Finally, in order to arrive at the marginal value-product of labor, the returns to other factors of production have been deducted from gross income. These deductions include a normal return, put at five per cent, on the estimated market value of farms. The input of both labor and capital per hectare is larger on the small than on the large farms, and market values of farms are not an adequate measure of the input of real capital. The smallholder accepts a relatively low remuneration for his own labor and capital, and it cannot, without arbitrariness, be determined to what extent this reflects a less than normal return to labor and to the capital invested in the purchase of a farm.

Also based on farm accounts collected and analyzed by the Danish Institute of Farm Management and Agricultural Economics, Knud Rasmussen [29] undertook a variance analysis of farm results and the calculation of agricultural production functions. The measure of farm results used is the net return expressed as a percentage of capital. The net return arises as the differences between gross income (including rent of the farm house and the value of products consumed in the farmer's own household) and the value of all inputs including imputed wages to the farmer and his family, but excluding interest on capital. In calculating the percentage return, two statements of capital value are used. One is the book value based upon tax valuations of all physical assets. The other, the market value, is an estimate of the price which the farm as a going concern could bring in the free market. This price is estimated by the accountancy consultant assisted by the farmer and is based on the current sales prices of similar farms in the open market.

It is found that for any single year the variance of financial results is reduced little by a classification of farms into regional and size groups. For any single year the total variance may be divided into two roughly equal parts, a random element and a so-called managerial element. If the financial results for each farm are averaged for several years, the importance of the random element is very much reduced, the managerial element accounting for by far the larger part of the total variance.

Whereas the variance analysis is based upon farm accounts for the 25 year period from 1925 to 1950, the production function study covers a five year period after the war. The coefficients of two Cobb-Douglas functions were determined: one in which net product is expressed as a function of labor and capital, and one expressing gross product as a function of the inputs of labor, capital, and raw materials. In the first function the author finds elasticities of 0.86 in respect to labor, and 0.19 in respect to capital, whereas in the case of the three independent variables, the elasticities found are 0.51, 0.13, and 0.39 in respect to labor, capital, and raw materials. Thus, in both cases the elasticities add up to slightly more than unity. While the inclusion of raw materials as an independent variable in the production function affects only slightly the extent of the residual variation, it has, of course, a great effect upon the regression coefficients for labor and capital. As it is found that on most farms raw materials have been utilized in suboptimal quantities and since variations in the input of labor and capital are associated with variations in raw material input, preference is given to the production function in the form with three independent variables.

On the basis of the production function analysis, the author investigated to what extent the ratio of gross product to total costs, including a return of four per cent on capital (estimated market value), was affected by the global combination of inputs and by the managerial variance, respectively. He reached the conclusion that the main factor in determining efficiency is the managerial element.

As in the case of the study by Gad, doubts may be raised as to the appropriateness and relevance of the capital concept used. Presumably the market value of a farm reflects an estimate of its future earning power and is not closely related to the present construction cost of real capital on the farm. When it is found in the variance analysis that taking periods of several years the importance of the random element in the variation of farm results diminishes rapidly, whereas the so-called managerial element becomes preponderant, it is possible that the influence of the managerial element is understated because in part the competence of the farmer is capitalized in farm value. On the other hand, it may be that estimates of farm values differ between farms in a way unrelated to managerial ability. In the concluding analysis of the relative importance of managerial competence and input combination to the ratio of gross product to total cost (including four per cent return on capital), the result found—the dominating influence on the managerial element—may in part merely reflect the fact that since costs are incurred in changing any established combination of real inputs, its efficiency affects the farm valuation, which measures the normal earning power of the farm rather than any aggregate of physical resources.

#### IV. *Price Theory*

Bjarke Fog [3] (1958) based a study of price policies on interviews with about 150 Danish industrial firms. Full cost calculation was found to be the procedure most frequently adopted with a view to long-run profit maximization as modified by other considerations. Thus, in some cases more importance appeared to be attached to the maximization of annual turnover than to that of profits. In large part, full cost pricing might be interpreted as a defense reaction against ignorance, concerning not only conditions of demand, but also of cost. E. Rasmussen [28] discussed the implications of firms using policy parameters other than price to promote sales in 1955. Most recently, 1963, E. Lykke Jensen [17], has made an important contribution to the theory of price determination under monopoly and imperfect competition. Price determination is analyzed on the basis of a stochastic model where the producer = seller considers demand as a random variable

with price as a parameter in the distribution function. In contrast to the deterministic case, it is here possible to define a supply function by equating marginal cost to marginal increase in sales expectations. Under certain rather restrictive assumptions, it may then be proved that equilibrium will be achieved at an appreciably lower price than in the non-stochastic case.

The economics profession in Japan today is rapidly expanding although the number of economists is still relatively small, probably less than 2,000 altogether, if we exclude specialists in business administration. It is no exaggeration to say that close to one-half of the economists in Japan today are of Marxist orientation.<sup>1</sup>

Academic Marxism became a substantial force in Japan in the late 1920's and the early 1930's just as the capitalist world was plunging into the Great Depression and the Japanese were moving in the direction of attempting to find violent solutions for internal ills via external aggression. Marxism offered a method of analyzing these problems in historical perspective; and in particular, it served as a unifying philosophy for a group of young, brilliant historians and social scientists who collaborated in the interpretive work on the origin and characteristics of Japanese capitalism. The dominant group among them, known

<sup>1</sup> One could verify this assumption through laborious enumeration. However, one shortcut would be to analyze the composition of the 30-member Third Division (Economics, Commerce and Business Administration) of the Japan Science Council, body of scholars elected every three years by the registered constituency of scholars in their respective divisions. The composition of the present panel, elected at the end of 1962, appears to show a slight majority of Marxian scholars, even though the panel includes representatives of the branch of "Commerce and Business Administration" who are overwhelmingly non-Marxist.

as the *Kōzō-Ha*,<sup>2</sup> and their works were duly suppressed by the militaristic government of the time. But they were an inspiration for many intellectuals who were opposed, either openly or more often secretly, to the policy of aggression pursued by the ruling clique of Japan. Although the method of analysis was imported from abroad, these Marxist scholars wrestled with the problem of interpreting the history of their own country, and a rich crop of by-products in the form of historiographic studies for the early Meiji period emerged. During this time, a minority of neo-classical economists were largely content with the work of what, in essence, was little more than the translation of western literature in the field.

The war period changed the apparent picture greatly but hardly affected the composition of Japanese economists in terms of their methodological orientation. While a large number of non-Marxist economists collaborated with the government in one way or another, most Marxists, either in jail or at large, turned their attention either to the highly academic study of doctrinal history, especially of the classical period, or to minute research in historiography, less that of Japan than of western countries.

### *I. Growth in Economic Thought in Postwar Japan*

The end of the war, naturally, saw extreme collaborator-economists purged from academic posts and the coming into the open, now with secured positions, of a large number of Marxist-economists from hiding that had been either enforced or voluntary. To all economists regardless of ideological orientation, the concrete problems of postwar Japan presented a challenge. Immediately there was a problem of inflation which, by the time it subsided in 1949, left the general price level at about 300 times that of 1934-36. Many of the tasks of adjustment which the defeated country was called upon to make were mainly economic in character: the need to absorb upwards of six million repatriates who were forced to return home from either civilian or military jobs in the countries which Japan had invaded; the need to reorient the structure of the economy from one which depended to a high degree on the international division of labor to one, at least for several years, of autarchic character; and so on. More important, however, were the basic tasks of reform. Ideas prevalent in the minds of policy advisers attached to the Occupation authorities at the initial period after the surrender were marked by a certain historical perspective which found a logical connection between the aggressive militarism of

<sup>2</sup> See Martin Bronfenbrenner, "The State of Japanese Economics," *Amer. Econ. Rev.*, 1956, XLVI (2), 389-98; especially pp. 390-1. The article, on the whole, is an illuminating study.

Japan and the peculiar socio-economic characteristics which had developed since the days of the Meiji Restoration (1868). At the time, these ideas were shared by a large number of the Japanese themselves—although common diagnosis did not usually lead to common therapy. In particular, it was agreed that something had to be done with the peculiar monopolistic structure of prewar Japan, the *zaibatsu*, which had been in collusion, if clandestine, with the military clique. It was also agreed that the agricultural sector of prewar Japan had lagged woefully in many aspects of the task of modernization and for this reason had been exploited by other sectors of the society in many ways. It was further agreed that the legacy of feudalistic mentality and institutions had its economic counterpart in the form of certain rigidities which prevented the mobility of labor and contributed to the persistence of dual structure in employment.

These and other problems, some short-run and some long-run, called for solution, at least an attempt at solution, in the minds of economists in the early postwar years. True, the role of the Japanese during the Occupation (1945-52) was secondary, often discouragingly so. Especially after the shift in the United States' policy on Japan in early 1948—a shift "from reform to recovery"—the erstwhile atmosphere of fluidity in the patient search for solutions disappeared and there came to be crystallized within Japan a social force which identified, quite rightly, the return to "normalcy" with rapid economic recovery. Nevertheless, here was a set of crucially important economic problems that deserved the close attention of Japanese economists, whatever methodology or conviction they might have followed. And yet it is questionable if they responded to this challenge with commensurate vigor and seriousness. Such a state of affairs calls for an explanation.

The basic cause, I venture to suggest, was a kind of scholasticism<sup>3</sup> which prevailed among the majority of Japanese economists at the time. Both the Marxian and the neo-classical (including the Keynesian) economists tended to depend on derived authority of one kind or another. For the Marxian group, the source of the authority was, of course, Karl Marx himself. At least in this case the source of the authority had long since been dead; any attempt at avoiding sterile scholasticism meant the confrontation of the method with the facts of life. Efforts to pursue such a confrontation, even if not too successful, generated the remarkable vigor of the Japanese Marxian group in the 1930's. However, the enforced hibernation of almost a decade made

<sup>3</sup>I coined the expression "doctrinology" (*Keisai-gaku-gaku*) at the time. If "economics" (*Keisai-gaku*) can be thought of as "a body of doctrines relating to economic facts of life," "doctrinology" would be a study of that body of doctrines as if such a study could replace "economics" itself.

many of the leading members of this group into doctrinal specialists, and the end of the war found most of them unprepared to cope with the burning problems of the day. Modern economists,<sup>4</sup> on the other hand, had the tradition of deriving their authority from recognized authorities abroad—who, needless to say, were on the move, with new stars and new ideas rising on the horizon. This situation kept modern Japanese economists moving, seldom however in a position other than following the path of pioneers abroad. Yes, they were on the move as “doctrinologists,” but most of them did not stop, as Ricardo and Keynes did, to concentrate on current economic problems of their own country. Thus again the end of the war found this group, to the extent they survived the immediate postwar purge, unprepared to offer their service effectively.

Nineteen years have now passed since the war ended. And the economics profession in Japan today presents a different picture. The division of the profession into the two groups still remains, but they are able to communicate with each other better. The erstwhile ailment, which Bronfenbrenner called “inbreeding,” still lingers, keeping intact the guild-like association of economists around respective masters. But here too, one cannot fail to observe a new trend of “intermarriage” on the rise.

What appears to be distinctly new, with dynamism of its own, is the shattering of derived authority among modern economists. Whereas the Marxian group still derives its authority essentially from the master of 100 years ago, “doctrinological” maturity helps the elders maintain their authority. The other group, however, has outgrown the tradition of derived authority and has produced a number of young economists who can stand on their own feet in the front rank of the economics profession of the world. Hiroshi Furuya, who died young in 1957, was probably the first to appear in this sense, and he was followed by a large number of young theoretical economists adequately trained in mathematics. In fact, one is struck by a sharp contrast in the list of Japanese contributors to *Econometrica* before and after what appears to be the distinct divide of 1951-52. The April 1951 issue of *Econometrica* printed a report of the Tokyo meeting at which the Japanese branch of the Econometric Society was organized. It is odd that practically all the participants who read papers on that occasion, except Michio Morishima, have not contributed any articles to *Econometrica* since 1952, and one gets the impression that the meeting was, most ironically, an occasion for transferring the baton from the old genera-

<sup>4</sup>This is the expression we shall use throughout this paper to denote all the groups of non-Marxian economists, such as the neo-classical, the Keynesian, the mathematical, and so on.

tion to the new. The new generation of mathematical economists, led by Morishima, progressed in the subsequent period with such suddenness and brilliance that very few of the generation now above fifty years of age could follow them. Since 1954 the pages of *Econometrica* have regularly seen contributions by young Japanese economists such as Morishima, Hirofumi Uzawa, Takashi Negishi, Hukukane Nikaido, Ken-ichi Inada, and others.<sup>5</sup> By now it may be said without exaggeration that it is in this field of mathematical economics, more than in any other, that Japanese economists stand in the front rank of the world's economists.

Along with this development of mathematical economics, there has emerged, with the mutually-reinforcing growth of statistical studies, a host of econometricians who have less respect for "doctrinology" than for facts. Among the latter are: Shin-ichi Ichimura in the field of input-output studies, Miyohai Shinohara and Tadao Uchida in the manifold econometric analyses of the Japanese economy, and many others who have given a new direction to a profession that is attracting an ever-increasing number of younger people.

In other words, there is new vitality gripping modern economists, with a younger generation rapidly replacing the old. Faced with this situation, Marxists are also on the move. While they seem to find it harder to extricate themselves from the tradition of derived authority, they are vitally concerned with the broader politico-economic work to which they are peculiarly suited and which by default escapes the attention of modern economists. They are equally concerned with the new problems arising from the experiences of numerous socialist countries which now occupy one-third of the globe. If we are to address ourselves to "major issues of theory and public policy arising out of postwar economic problems in Japan," we shall find that the discussion of the major problems of reform, such as *land reform* and *anti-monopoly measures*, has been conducted largely by the Marxist economists. At the same time, the problem of the *growth-rate* has been

<sup>5</sup> Morishima's first contribution to *Econometrica* in full-length article form was "Consumers' Behavior and Liquidity Preference" in the issue of April 1952. All others started contributing since 1954. Some of the titles may be mentioned here: Morishima, "Prices, Interest and Profits in a Dynamic Leontief System" (July 1958), "Some Properties of a Dynamic Leontief System with a Spectrum of Techniques" (October 1959), "Economic Expansion and the Interest Rate in Generalized von Neumann Models" (April 1960); Uzawa, "Prices of the Factors of Production in International Trade" (July 1959), "Market Mechanisms and Mathematical Programming" (October 1960), "The Stability of Dynamic Processes" (October 1961); Negishi, "The Stability of a Competitive System: A survey Article" (October 1962); Nikaido, "On the Programming of Nonlinear Production Functions" (January 1954), "Stability of Equilibrium by the Brown-von Neumann Differential Equation" (October 1959); Inada, "Alternative Incompatible Conditions for a Social Welfare Function" (October, 1955).

mostly the concern of modern economists, with the issues related to the *dual structure* of employment commanding the attention of both. Meanwhile, the task of producing and collating *statistical series* of all kinds has fallen mainly on the shoulders of economists and statisticians within the government. The subject matter italicized above will form the topics of discussion in the pages to follow.

## II. *Land Reform*

The postwar land reform of Japan (1946-1950) is often cited as an example of the few reforms which were initiated and directed by the Occupation and yet survived "the back to normalcy" reversal of the subsequent period. The reason for this is not hard to find. Instead of having to impose alien ideas on a reluctant population, the Occupation found both academic and administrative experts on agriculture in Japan eager and competent to carry out a type of reform the Occupation had envisaged. In prewar Japan, numerous volumes of research and analysis were published that showed the mechanism through which the peculiarly parasitic character of Japanese landlordism contributed to solidifying the hold of militarism upon the country. About one-half of the cultivated land was under tenancy, each tenant family cultivating, with little incentive from modernization, slightly over two acres on the average and paying *in kind* the exorbitant rent of more than 50 percent of the gross product. The bare subsistence condition of the tenant class induced them to supply labor from their families to urban factories at an extremely low wage rate, thus setting the tone for the wage level in manufacturing in general. In other words, it was clear that *economic* democracy could not be brought about without a drastic change in the tenancy situation in agriculture. Suggestions for reform had been *in utero* among the Japanese themselves even before the war; and the role played by the Occupation, having uncontested political authority, was essentially that of a midwife.

The land reform consisted of: (a) the forced sale by landowners to the government of land above a certain maximum<sup>6</sup> at a price based upon the official price of rice in 1945;<sup>7</sup> (b) the sale by the government of thus purchased land to the tenant class as well as to the less-than-minimum landowners at a nominal price; (c) the setting of a legal maximum on rent, now to be paid in money, at a level which in effect turned out to be less than three percent of the gross produce per area; and (d) the establishment of Agricultural Land Committees in each

<sup>6</sup> Zero for absentee owners and 2.45 acres for resident owners except those in Hokkaido, who were permitted to retain 9.8 acres.

<sup>7</sup> The official price of rice rose more than one hundred times between 1945 and 1949. Black market price, of course, was higher than the official price throughout this period.

locality, with a greater representation for the former tenant class than for the landowners, to supervise the faithful execution of the reform. The reform was carried out faithfully, reducing the tenant-cultivated area to 9.4 percent of the total by 1950, and weakening markedly both the economic and political powers of the former big landowning class. Average area cultivated per family came down slightly to something less than two acres. However, it cannot be doubted that a major transformation in Japan's rural structure took place here—a transformation from a rural life largely characterized by poverty-stricken tenants to one consisting predominantly of small cultivating landowners who were given the incentive, as well as the capacity, within limits, to improve their lot.<sup>8</sup>

As soon as the reform was launched, an academic controversy arose that focused on the problem of whether the reform did imply a kind of revolution in rural areas for economic and political democracy. The erstwhile *Kōzō-Ha*, mentioned earlier, and their followers, who were the most ardent advocates of a thorough-going land reform, were apparently dissatisfied with the extent of the reform, and pointed out in particular that: (a) The Land Reform Act of 1946 did not touch the extremely skewed distribution of forest-land ownership, leaving the economic power of big landowners intact; (b) non-cultivating landowners could still exploit tenants if the ownership was within the maximum set by the Act; and (c) in any case, the average total area cultivated by a single family, often fragmented over a wide area, was still so small that there was little hope of raising one's standard of living as a farmer. Negative views of this type were rather prevalent in the early stage of the reform and are best represented by the writings of Haremaru Inoue, which constituted a part of the ambitious eleven-volume series called *Nihon Shihonshugi Kōza* ("Study Series on Japanese Capitalism").<sup>9</sup>

Against such negative views was pitted a positive one championed especially by Hyakuju Kurihara, whose *Gendai Nihon Nōgyō Ron* ("A Treatise on the Japanese Agriculture Today"), 1951, could be counted as a classic in this field. Kurihara discusses the political sig-

<sup>8</sup> The most objective, thorough-going account of the land reform can be found in Nōchi Kaikaku Tenmatsu Gaiyō ("General Account of the Instituting of the Land Reform"), edited by the Committee for Recording the Land Reform, 1951. The study was sponsored by the Ministry of Agriculture and Forestry, mobilizing several score of experts in the field. It gives an accurate account of the legislative process which gave birth to the Land Reform Act of 1946, traces in detail how the Act was carried out, analyzes the consequences of the reform, and is concluded with a discussion on the historical development of the land tenure system in Japan.

<sup>9</sup> Published by Iwanami Shoten in 1953-54. Inoue's contribution, "The Land Reform and the Semi-Feudal Character of Japanese Capitalism" is included in the fifth volume of this Series published in 1953.

nificance of the reform apart from its economic significance. Political significance, according to him, lay in "uprooting the basis for ultra-nationalistic ideology as well as in providing an effective buffer against communistic encroachment." As for the economic significance, Kurihara emphasized the consequent liquidation of the semi-feudal type of exploitation on land based upon the status-power of the big landlord class and the 50-60 percent rent extortion in kind. It was admitted that rich farmers still existed after the reform, deriving their income from large forest areas and/or from commercial and financial activities of all sorts. But their economic power came to be blended, much more so than ever before, with the interests of the capitalistic class as a whole. In other words, Kurihara maintained that through the land reform Japanese capitalism became more integrated and more rationalized.

The controversy between the two opposing views above, which dominated the scene in late 1940's and early 1950's, ended with the gradual retreat of the negative view. It is difficult now to find an expert in the field who would still maintain that the Land Reform Act of 1946 accomplished little or nothing. Meanwhile, however, the positive view, held typically by Kurihara, also has come to be modified. For one thing, while the major debate was going on, empirical research of all kinds on different aspects of Japanese agriculture was being carried out quietly by scholars, not only of Marxist orientation, but also of non-Marxist.<sup>10</sup> Then again, as reshuffling in the initial decade of the reform was completed and the rural area became stabilized with the post-reform configuration in ownership, production, and trade, a new set of problems arose. In a way, it was to be expected that this would be the case. As the agricultural scene became uniformly characterized by small proprietorship, the competition in the introduction of labor-saving machinery and other cost-reducing devices was heightened. By 1958 this trend went through a cycle as far as it could within the given

<sup>10</sup> A group of Marxists, called the *Rōnō-Ha*, which was opposed to the *Kōsō-Ha* in the 1930's had held that the Meiji Restoration (1868) was essentially a bourgeois revolution, which implied that Japanese agriculture had already liquidated the remnants of the feudal period at the time of the Restoration. If one holds this view, one is prone not to lay too much emphasis on the significance of the postwar land reform. Thus the economists who belonged to the *Rōnō-Ha* were much less active than others in participating in the controversy referred to above and instead busied themselves with empirical research of all kinds. The most notable among them is Tsutomu Ōuchi, whose *Nihon Nōgyō no Zaiseigaku* ("Japanese Agriculture and Public Finance"), 1950, is an undisputed classic. But more recently a most ambitious work of collective research has come out under the general editorship of Seiichi Tobata, *Nihon Nōgyō no Zenbō* ("A Complete View of Japanese Agriculture"), 1956-61, which in five thick volumes deals with practically all the aspects of Japanese agriculture, mobilizing again several score of experts of different ideological orientation. Among the works by non-Marxist economists we should not fail to mention the energetic contribution by Kazushi Ohkawa whose *Nōgyō no Dōtai Bunseki* ("Dynamic Analysis of Agriculture") 1954, is an exemplary sample.

production function. There is no doubt that productivity in agriculture rose markedly during the post-reform decade. But at the same time it has become clearer than ever that the limitation in the scale of operation, which on the average has shrunk to less than two acres even when the total family holding is added together, is beginning to tell. A two-acre farm can use only a limited-sized mechanical plough economically. While the marginal productivity of capital is thus showing itself to be rapidly on the decline, the low income elasticity of demand for rice and other agricultural commodities is affecting the demand side unfavorably. Theoretically, this is a situation that should induce a movement of the labor force from agriculture to industry if the manufacturing sector is growing rapidly at the same time. In fact, the latter has been flourishing at an unprecedented rate during the past decade. Yet the total number of agricultural households remained more or less stationary between 1950 and 1960, declining only slightly from 6,176,000 to 6,025,000. By 1959, it has been estimated, the average real consumption level of agricultural families rose by 45 percent compared with the prewar normal, whereas that of urban families rose by less than 30 percent. The trend now appears to be being reversed. Even with the sizable annual deficit in the special budgetary account of the Basic Food Control Bureau, which absorbs the negative margin between the producer's price and the consumer's price of grains, the agricultural class is finding it extremely difficult to maintain the *income* parity with the wage-earning class. Problems involved here are legion; and the attention of economists is directed more and more to this new focus which threatens to be of as grave dimension as that of the recent land reform.<sup>11</sup>

### III. *Anti-Monopoly Measures*

It has been observed by many that the twin economic pillars which supported Japanese militarism were the semi-feudal form of exploitation in agriculture and the unique monopoly structure called the *zaibatsu*. Thus the program for economic democratization in Japan after the war immediately placed on its agenda two basic problems of reform: the distribution of land to the landless and the dissolution of the *zaibatsu*. Of the two, the former was the easier since land reform was considered not only as a matter of social justice, but also as conducive to better economic performance in agriculture. Anti-monopoly

<sup>11</sup> The Basic Agricultural Problem Research Commission, appointed by the government, has been wrestling with this problem and has made public an interim report on their deliberation, *Nōgyō no Kihon Nondai to Kihon Seisaku* ("The Basic Problems and Policies for Japanese Agriculture"), 1960. This report became the basis for the Agriculture Standards Act of 1961.

reform, on the other hand, was much more complex. Here, for one thing, the thinking of the Occupation was not in agreement with that of Japanese experts in the field—for the very reason that the objective was different.

In the initial period of the Allied Occupation, the problem of the *zaibatsu* presented itself to the occupying authorities less as a question of hindrance to democratization or to rational allocation of resources than as an object of censure for presumably having worked hand in glove with the militarists in an unholy alliance to conquer the world. In addition, the Occupation policy was originally oriented toward keeping Japan's standard of living below that of any of the countries which she had invaded.<sup>12</sup> If the nation's standard of living was to be artificially restricted to a level below its own potential, the matter of attaining maximum economic efficiency could not be of prime consideration. Practically all the anti-monopoly measures under the Occupation were put into effect during this initial period, that is, before the end of 1947. The terms of reference were contained in the directive of the President of the United States, dated September 6, 1945, which favored "a program for the dissolution of the large industrial and banking combinations which have exercised control of a great part of Japan's trade and industry." First, the key holding companies at the apex of the *zaibatsu* structures were required to transfer their stocks to the Holding Company Liquidation Commission to be disposed of to the general public on the open market. Then came the Anti-Monopoly Law, incorporating, somewhat mechanically, many of the features of American antitrust legislation and designed to prevent reappearance of any of the steps tending toward monopolies. A Fair Trade Commission was created under this law. The last of the measures was the Elimination of Excessive Concentration of Economic Power Law which passed the Diet, under strong pressures from the occupying authorities, on December 18, 1947. The law, without setting up any clear-cut standards or criteria, conferred upon the Holding Company Liquidation Commission the authority to order the dissolution or reorganization of any corporation whose size or structure could be described as partaking of the character of "excessive concentration of economic power."

As long as the anti-monopoly measures were based on the sense of retributive justice, and to the extent they were alien in philosophy and were hastily pushed down the throats of unwilling Japanese, their effective life was destined to be short. Actually, the turning point came rather early. It was heralded by the famed speech, on January 6, 1948,

<sup>12</sup> The Far Eastern Commission raised in April, 1947, the "permissible" standard of living of Japanese to their own 1930-34 level. In real terms, this was probably about three times the level of the poorest victim nation in Asia.

by Mr. K. C. Royall, U.S. Under-Secretary of Army, in which he called for a re-examination of America's attitude toward Japan, saying that the new conditions in world politics had produced "an inevitable area of conflict between the original concept of broad demilitarization and the *new purpose* of building a self-supporting nation." (Italics added.) The speech was rapidly followed by General McCoy's statement at the Far Eastern Commission (January 21, 1948), the so-called *Strike Report* drafted for the U.S. Department of Army by the Overseas Consultants Incorporated (March 2, 1948), and the Report of the Johnston Committee (May 19, 1948) which concluded that the United States should, in its own interest, now assist in the industrial recovery of Japan. Once the tide was turned, whatever measure appeared, or was alleged by the Japanese business world, to retard the recovery was either watered down or suspended. The reparation target was drastically cut and the implementation of anti-monopoly legislation became secondary to the need of utilizing the existing organization of industries to the fullest advantage. The fact that the enactment of these laws was not voluntary on the part of Japanese hastened the atavistic process further. The Deconcentration Law was never seriously put into effect. The Anti-Monopoly Law was soon revised to permit a manufacturing corporation to hold shares of competitive firms, to raise the upper limit of shareholding by financial institutions from five to ten percent, to legalize again the system of interlocking directorates, and to widen the scope of cartels that could be formed. It was almost natural that the "back to normalcy" trend finally found its way in the consolidation and realignment of firms along the former *zaibatsu* lines. Their trade names, such as Mitsui, Mitsubishi, Sumitomo, and so on, which had been once barred from use, were revived after Japan regained its independence in 1952; and the forced separation and splintering of their erstwhile integral structures have been largely repaired. True, there are no longer holding companies at the apex which had been characteristically controlled by respective *zaibatsu* families. In their place, however, has emerged the central role played by the bank of each group, such as the Mitsui Bank for the Mitsui group, and also a new coordinating organization of presidents of firms belonging to the same group. It appears that all the effort put into the anti-monopoly aspect of the economic democratization program almost came to nought.

The lack of success in the anti-monopoly effort was probably most apparent from the standpoint of the designers of the program on the Occupation side. But those Japanese economists who concerned themselves with the monopoly issue had a different approach from the outset and thus were neither disappointed nor pleased by the "back to normalcy" outcome. In a word, their concern had been broader. Most

of them never doubted the positive contribution of *zaibatsu* to economic growth and efficiency within the context of Japanese capitalism. By internalizing external economies, by distributing risk, and by being able to afford large scale industrial research, the *zaibatsu* played a role which is almost exactly like the one Rosenstein-Rodan assigned to his suggested Trust for industrialization of underdeveloped countries.<sup>13</sup> For the Japanese economists who wrestled with the problem of monopoly in their own country, the criticism of monopoly implied necessarily a criticism of capitalism. For the Japanese economist, the alternative was not between monopolistic capitalism and competitive capitalism, but rather between capitalism and socialism. A tremendous number of professional works exist, dating back to 1930, which probe analytically and empirically into the mechanism of the dynamic interrelations of the military, the bureaucracy, and the monopoly. These works are, for the most part, Marxist-oriented. But the fact is that their analysis and prediction were borne out by the course of events in the 1930's. When such is the case, it is to be expected that the proponents of the successful hypothesis will persist in holding on to their methodology.

This is the setting in which the problem of anti-monopoly measures presented itself in postwar Japan. What we might call the Occupation ideology on this matter received relatively little attention from Japanese economists except to the extent to which a few of them were directly involved in the administration of the Holding Company Liquidation Commission and the Fair Trade Commission. A major part of the research done in this connection was by the civil servants concerned and usually consisted of a compilation of historical accounts such as *Nihon no Zaibatsu to sono Kaitai* ("The *Zaibatsu* in Japan and their Liquidation"), 1950, by the Holding Company Liquidation Commission, or a series of straightforward factual surveys similar to those published by the Fair Trade Institute.<sup>14</sup> As a slightly more interpretive work, we should probably mention *Mitsui-Mitsubishi-Sumitomo: Present Status of the Former Zaibatsu Enterprises* (in English), 1955, edited by the Mitsubishi Economic Research Institute, which despite its *zaibatsu* name has the tradition of objective economic research.

On the other hand, works by Marxist-oriented economists on the

<sup>14</sup> This is the institute which was established within the Fair Trade Commission apparently in order to avoid restrictive budgetary controls over publications, for sale, of the research done by the staff of the Commission. There exist many studies by them on concentration ratios of different industries as well as on the mode of concentration in the banking and financial sector. Since 1957, the Institute has been publishing, in English, a quarterly journal called *Fair Trade*, which often contains extremely revealing articles.

problem of monopoly are too numerous to list here. Aside from the ideological issue<sup>15</sup> relating to the character of monopoly capitalism in Japan today, which is being disputed among themselves, their major efforts appear to have been directed thus far to two groups of problems: (a) the manner in which monopolistic regrouping has been taking place and the nature of new monopolistic control devices; and (b) detailed industry studies. The latter are mainly empirical, and as such, Marxists have no monopoly on the subject. In fact, this is the field where economists with differing orientation, along with engineers and others in business, could cooperate. The outstanding example of such a cooperative work is *Gendai Nihon Sangyō Kōza* ("Study Series on Industries of Present-day Japan"), 8 vols., 1959-60, under the general editorship of Hiromi Arisawa, a distinguished economist with a Marxist orientation. "Study series on industries" suddenly became a fashion after 1958 and there are at present five others in process, with differing emphases and ideological orientation. However, it is natural that the monopoly aspect is treated as an integral part of such industry studies only in the Marxist-oriented studies.

Since the Occupation shifted its policy on Japan toward encouraging rapid economic recovery, Marxist economists predicted that the *zai-batsu* form of monopolistic structure would re-emerge. Thus they followed closely the turn of events and, step by step, the manner of regrouping and consolidation in business organizations. The focus in these studies was directed toward interfirm relations of all kinds, such as: holding of equity shares in competitive and/or complementary firms; interlocking directorates; membership in a specific coordinating organization of corporate managers; bias in financing by a particular bank toward certain firms; and so on. This type of monopoly study may be classified as "physiological" in contrast to the "anatomical" in which a major tool of analysis would be the concentration ratio in a particular industry.<sup>16</sup> The number of economists who concern them-

<sup>15</sup> What should be the politico-economic characterization of the present-day Japanese capitalism is their problem. One group, represented by *Nihon Shihonshugi Kōza*, *op. cit.*, maintains that it is essentially a dependency to the United States. Another group, represented by *Gendai Nihon Shihonshugi Taikēi* ("A Systematic View on Contemporary Japanese Capitalism"), 7 vols., 1957-58, maintains that the class conflict between the monopoly capital and the working class is the overriding feature. This group continues the tradition of the so-called *Rōnō-Ha*. A third group, represented by *Gendai Nihon no Seiji to Keizai* ("Politics and Economics of Contemporary Japan"), 4 vols., 1958-59, maintains that the threatening revival of Japanese imperialism is the key to the present situation. Naturally, each one of the three has its own unique policy implications. Thus the issue is being fought rather bitterly.

<sup>16</sup> A detailed work of the "anatomical" type, based upon the statistics supplied by the Fair Trade Commission, is best represented by Hitoshi Misonou's *Nihon no Dokusen Shihon* ("Monopoly Capital in Japan"), 1960.

selves with the "physiology" of Japanese monopolies is large,<sup>17</sup> bringing out one case study after another on the trees in the forest, but not yet, it seems, coming to a point where the entire forest can be viewed in historical perspective. At least, however, they appear to agree generally that what is emerging is not a simple replica of the old *zaibatsu* form but something more rational in interfirm relations than existed under the old regime.

#### IV. *The Debate on the Growth Potential*

It is probably no exaggeration to say that the debate on the growth potential of the Japanese economy was the most important event in the circles of professional modern economists<sup>18</sup> in postwar Japan. This discussion, which gathered momentum from 1958 onwards, involved theorists and statisticians as well as policy-oriented economists, and academic economists as well as government and business economists. Participants in the debate, in the sense of having contributed at least one article on the subject, probably number fifty or more, which implies that there are at least that many articles and/or books in print thus far. By general consensus, the star of the debate is Osamu Shimomura, a government economist at the time the debate began, who attracted general attention through his extremely optimistic views and also through the fact that he has been an important member of Prime Minister Ikeda's brain trust for a number of years.

To be exact, we must say that the debate began when the government *Economic White Paper* came out in 1957 with the catch phrase: "*mohaya sengo dewa nai!*" ("Special factors of the postwar period can no longer be relied on.") Theoretical support for this premise was supplied by Miyoei Shinohara, who, relying mainly on the statistical evidence, advanced a thesis that a country enjoying a rehabilitation boom after the war was likely to experience a sudden shift in its rate of growth. Japan's growth rate in real GNP averaged at 11.3 percent between 1946 and 1951, but dipped rather markedly to 7.7 during 1951-56, and was expected to fall, according to M. Shinohara, to 5 percent or thereabouts after 1956. The *Economic White Paper* of 1957 gave assent to this view. However, when the so-called "New Long-Term Economic Plan" was drafted toward the end of 1957 as a prospectus for the five-year period of 1958-63, the rate of growth of real GNP

<sup>17</sup> A few studies along this line may be mentioned here: Yoshio Kobayshi (ed.), *Kigyō Keiretsu no Jittai* ("Empirical Studies on Grouping of Firms"), 1958; *Nempō Keiretsu no Kenkyū* ("Annual Report on Studies on Grouping") edited by Keizai Chōsa Kyōkai (Economic Research Association); Iwao Kunitatsu, *Nihon Kogyō no Kōzō* ("The Structure of Japanese Industries"), 1960; Giichi Miyazaki, *Dokusendō Sokutei no Shomondai* ("Problems Arising in the Measurement of the Degree of Monopoly"), 1961.

<sup>18</sup> Non-Marxist economists.

was hypothesized as 6.5 percent; and most people felt that this was too ambitious. Shimomura was probably a sole exception among economists at that time to criticize the target as too low. He proposed the 10 percent annual rate as an easily feasible one.

An important part of Shimomura's reasoning was a recognition of an historical upheaval in the investment function of the Japanese business world and in the consumption function of the Japanese people. Schumpeter would probably have called such a conjuncture the coinciding of a Kondratief upswing with a Juglar prosperity. However, Shimomura formulated the original version of his theory rather crudely by using a simple Domar-type model. First, the net increase in output capacity maturing in any particular year is considered to be roughly equal to the private gross capital formation in plant and equipment in the preceding year. This implies:

$$(1) \quad GNP_t - GNP_{t-1} = \sigma \cdot PGCF_{t-1}$$

where  $PGCF$  stands for private gross capital formation in plant and equipment, and  $\sigma$  for the productivity of such addition to capital. Dividing both sides by  $GNP_{t-1}$  and substituting the assumed value of unity into  $\sigma$ , we obtain:

$$(2) \quad \frac{GNP_t - GNP_{t-1}}{GNP_{t-1}} = \frac{PGCF_{t-1}}{GNP_{t-1}}$$

which means that the rate of growth of  $GNP$  is equal to the ratio of private gross capital formation in plant and equipment to  $GNP$ . In any particular year we first obtain the projected value of  $PGCF$  and then its preliminary estimate along with the preliminary estimate of  $GNP$ . These figures provide the government with a guide to measures needed to stimulate effective demand (social overhead capital and so on) in order to obtain equilibrium growth. The only danger in the policy of making  $[GNP_t - GNP_{t-1}]$  equal to  $PGCF_{t-1}$  in a country like Japan could come in relation to the balancing of international payments. Shimomura, however, found no ground for fear in this area. His formulation of the problem was:

$$(3) \quad \begin{aligned} \Delta M &= m \cdot \Delta GNP \\ \Delta X &= e \cdot g_w \cdot X \end{aligned}$$

where  $M$  and  $X$  stand for foreign exchange debit and credit respectively,  $m$  the marginal propensity to import,  $g_w$  the rate of growth of world income, and  $e$  the elasticity of Japan's exports with respect to world income. The condition for  $\Delta X \geq \Delta M$  is obviously:

$$(4) \quad e \cdot g_w \cdot X \geq m \cdot \Delta GNP$$

If we divide both sides by  $GNP$ , we obtain:

$$(5) \quad e \cdot g_w \frac{X}{GNP} \geq m \cdot \frac{\Delta GNP}{GNP}$$

Shimomura estimated  $m$  to be about 9 percent or less,  $e$  to be between 3 and 3.5 and  $g_w$  to be at least 3 percent. If we take the lower figure of 3 for  $e$ , the condition is simplified to:

$$(6) \quad \frac{X}{GNP} \geq \frac{\Delta GNP}{GNP}$$

In other words, the upper limit of the growth rate of  $GNP$  is the ratio of exports (or gross receipts in foreign exchange accounts) to  $GNP$ , which in the case of Japan is usually above 10 percent.

It was easy enough to find fault with Shimomura's initial presentation of the problem. In particular, the specific magnitudes he assigned to parameters  $\sigma$  and  $m$  were called into question. The crude hypothesis of a lag of one year in the maturing of capacity creation was also scrutinized. The stability of the value of  $e$  was doubted. Indirect productivity effect of social overhead capital was suggested; and so on. The most lively period of debate was from 1959 to 1960, a period which coincided with the phenomenal rise in Japan's real  $GNP$  of 17 and 10 percent respectively in its annual rate. In answer to numerous criticisms, Shimomura did modify his original model somewhat. But supported statistically by the actual fact of rapid growth and politically by Ikeda, who became Prime Minister in 1960, Shimomura has retained his role as the oracle of optimism (11 percent or higher annual rate of growth in real  $GNP$  up to 1970), and is now mobilizing revised statistics to support his argument.<sup>19</sup> Meanwhile, Prime Minister Ikeda, confident of his brain trust's vision and reasoning, made it government policy to double Japan's real national income in ten years (implying a 7.2 percent annual growth-rate) and has been setting the tone of optimism in the climate of business expectation. Thus the debate is no longer academic. It has become a political one as well. It continues with new ramifications developed and different angles opened.<sup>20</sup>

<sup>19</sup> In particular, see his paper presented at the Nagoya Meeting of Japan Theoretical Economics Association in October 1960.

<sup>20</sup> Since the debate has been eminently topical, most of the publications on the subject have been in the form of articles. But two books, bearing directly on the debate, have come out: *Nihon Keisai no Seichōryoku* ("Growth Potential of Japanese Economy"), 1959, edited by Kin'yū Zaisei Jijō Kenkyū Kai (Research Association on Monetary and Fiscal Matters), incorporating the most important articles by Shimomura and his critics; and *Nihon Keisai no Seichō* ("The Growth of Japanese Economy"), 1960, supervised by Ichirō Nakayama, containing the stenographic record of a symposium held on the subject in January 1960 and also a concise summary account of the debate up to the spring of 1960.

One of the side issues in the debate from the very beginning has been the question involving disaggregation. It was asked: Assuming that it is possible to maintain a high growth rate, what will be the effect on different sectors of the economy, in particular, the effect on different classes of people? Will not a rapid growth in a capitalist country like Japan necessarily mean a high profit prosperity and an increasing skewness in the size distribution of income? Defenders of the Shimomura thesis maintained that a rapid growth would be the very thing which could solve all kinds of structural imbalance. The solution for the rush-hour crowd of commuter trains is to increase the number of cars operated—such was the simile they used. Against this, critics pointed out the structural characteristics of Japanese capitalism and the manner in which they tend to become perpetuated under the conditions of capitalistic prosperity. One such characteristic—the dual structure of employment—has long been an important subject of study and debate in Japan and therefore is to be independently dealt with in the next section.

### *V. Dual Structure of Employment*

Dual structure of employment—a term that is used rather generally—probably requires a closer description as it is applied to the Japanese context. In brief, it refers to a duality in the labor market, but certain peculiar elements in the Japanese situation are worth mentioning. Let us take the sector of manufacturing industries as our example. All the establishments in the sector can be divided, fairly distinctly, into two groups: up-to-date large scale firms on the one hand and technically-lagging small firms on the other. The former recruits workers from recent graduates of schools at a wage rate not necessarily different from the prevailing one for new entrants anywhere. Once they are hired, however, they become “permanent employees” of the establishment—not to be fired or laid off until retirement age. They become the core of the working force in a particular establishment and rise in position and pay automatically with age. Since they are not to be laid off even in time of slack business, the management limits their number to the minimum and supplements them by a substantial number of temporary hands even in ordinary times. These temporary employees are of two kinds: (a) those who are usually hired for a stretch of more than a month and remain as stand-bys for a particular firm even when they are idle, and (b) those who are hired by the day. Even these cushions may not be sufficient to meet the severity of fluctuations at times. Thus large firms usually cultivate around themselves a fair number of small firms as a type of putting-out system. (There are, of course, other reasons for the viable existence of small firms.) Workers in these small

firms, whether or not they are directly associated with a large parent firm, are usually recruited locally and/or nepotistically, they come perhaps from farms, from among older men, and sometimes from recent graduates of schools. In other words, the labor force in manufacturing can be divided more or less distinctly into two groups: (a) permanent employees of large firms, and (b) others. It is most significant that there is practically no mobility between the two. It is also to be noted that, aside from the similarity in the starting wage, the wage scale differs greatly between the two groups.

The duality referred to has been the subject of discussion for many years in Japan, and the problem of mitigating its undesirable effects, if not its dissolution, has been prominent on the agenda of the postwar Japan's democratization. It might have been thought that the mushroom growth of trade unions, coupled with the enlightened policy of the government, would have the effect of promoting progress in the modernization of the labor market. However, the achievement of this aim thus far has been less than satisfactory. For one thing, unions have touched mainly upon the category of workers belonging to "permanent employees" of large firms, and their success in raising wages has tended to widen the wage differential between the two layers of the labor market. Here is a paradoxical situation of organized workers in large firms sharing in the productivity rise with the monopoly capitalists who tend to exploit their small subsidiary firms, which in turn can survive only by exploiting their nonunion workers to the utmost. This is a paradoxical situation, indeed, especially when we reflect upon the fact that the organized workers in large firms are the most radical elements in Japanese politics, while the unorganized workers in small firms have been shown generally to share the politically conservative views of their employers. The paradox, however, is resolved once we shift our focus to the sociology of the situation. The system of "permanent employees" in large modern establishments has its roots in the patriarchal tradition of Japan, just as the same can be said of the family-like atmosphere of small firms, which inhibits the growth of trade unions requiring impersonal, matter-of-fact attitudes to defend individual rights. The duality in market structure, which may be said to have its economic logic in the fact that both the modern sector and the small-size sector complement each other for respective viable existence, goes hand in hand with the duality in employment structure which is a part of the sociological picture of present day Japan. None of the essential aspects of this entire situation can be dealt with in an isolated manner. Thus the task for labor market modernization, though superficially amenable to *ad hoc* measures narrowly directed to the purpose at hand,

unavoidably involves a whole range of problems where improvement will take time.

Such is the background against which many economists with differing interests have tackled the problem of the dual structure of employment in the postwar period. In particular, it should be noted that it was two American economists who provided an entirely fresh approach to the problem and made Japanese colleagues realize the peculiarities of the Japanese situation, which tended to be taken for granted by the Japanese themselves. They were J. Abegglen (*The Japanese Factory*, 1958) and S. Levine (*Industrial Relations in Postwar Japan*, 1958). Among the Japanese economists, on the other hand, Kazuo Ohkōchi led a school of his own, as it were, to delve into the problem both historically and statistically. He has laid special emphasis on the characteristically historical origin of Japanese wage labor, namely, that most of the men who came from farms to cities to work in factories did so as bachelors with their family roots on the farm still intact. Thus employers could hire them initially at a price that was equivalent to the subsistence of a single young man. It was customary for the employer to incur cost in training his workers in their skill, and as protection against having his trained men enticed away from his firm, the employer would make it a practice to raise wages by a seniority system. As the worker became established in a city, married and had children, his subsistence needs rose, and the adjustment in wage rate usually took the form of family allowances. It is easy to see that such a wage system induces workers, even when unionized, to be concerned mainly with bargaining with respective firms and never on an industry-wide basis—thus the so-called system of the firm-by-firm union. Kazuo Ohkōchi and his younger colleagues have been studying this entire problem in a systematic fashion and during the past decade have published a large number of theoretical works and statistical studies. Probably the most representative among these studies is S. Ujihara, W. Fujita and N. Funahashi, *Nihongata Rōdō Kumiai to Nenkō Chingin Seido* ("Trade Unions Peculiar to Japan and the Wage System by Seniority"), 1960. Ohkōchi himself has numerous articles to his credit.

Peculiarities of the labor market have their counterpart in the size-structure of firms which provide the demand for labor. The size of a firm is not only a function of the nature of the industry but is subject to a bias rooted in the monopoly structure of the economy, with both the government and banks favoring the larger firms over the smaller ones. Here is an instance, one may say, of circular causation à la Myrdal. If it is true that within one and the same industry Firm A can generally pay a higher wage than Firm B, it must be due to the fact

that Firm A's value added per worker is higher than that of Firm B; such a difference in turn must be due to a difference in capital intensity. Reasoning of this nature leads us to look into the difference in the facility with which different firms are able to obtain capital funds. The best of the studies which pursued this line of thought empirically, with highly illuminating results, are found among the research of government economists and of economists like Miyoei Shinohara, who is often an adviser to government economic agencies. In particular, we might mention *Shihon Kōzō to Kigyō-kan Kakusa* ("Capital Structure and Inter-Firm Differentials"), Research Series No. 6 of the Institute of Economic Research, Economic Planning Agency, 1960; and among Shinohara's works *Sangyō Kōzō* ("The Structure of Industries"), 1959, is representative of this approach.

The problem of the dual structure of employment has had another focus in intensive empirical studies in the postwar period, namely, problems pertaining to small and pigmy-size firms. Here the problem is concerned not only with that of employed workers but also with that of employers themselves—especially if the latter are individual proprietors. The interest in this aspect of the Japanese economy was heightened markedly in the postwar period, especially among that circle of Asian economists who saw in the prevalence of small and pigmy-size firms in fast-growing Japan a positive solution for a country that still suffers from surplus labor and yet is attempting to industrialize rapidly with modern labor-saving techniques. Most of the Japanese economists who specialized in the problems of small and pigmy-size firms were skeptical of the emulative quality of their subject matter. However, it cannot be doubted that the inquiries from abroad stimulated a renewed interest in the subject and placed it in a broader framework for discussion. Whereas in the prewar days the subject was looked upon more as a peculiarly Japanese problem—somewhat in the manner Americans would deal with the Negro problem in the South—the context has now widened into the possibility of generalizing certain aspects of the problem. In other words, the subject matter has become a concern of theoretical economists as well as of economists with a more practical approach. With such an atmosphere in the background, large numbers of studies with differing emphases have appeared in the field. Three study series in particular are worthy of note. The first is the product of the Small and Pigmy-Size Industry Committee of Nihon Gakujutsu Shin-kō Kai (Japanese Association for the Promotion of Sciences) which succeeded in mobilizing economists from both Marxist and non-Marxist groups, and so far has brought out six solid volumes on different aspects of the problem. The second series, edited by Kiichi Isobe, Ichiro Nakayama, Hiromi Arisawa, and Ichiro Oshikawa, has also been pub-

lished in six volumes with a much greater emphasis on the statistical and empirical sides, while the third series of four volumes is patently of Marxist orientation.

#### VI. *Advances in Economic Statistics*

Prewar Japan was not especially distinguished for its abundance of economic statistics. Fiscal, monetary, and foreign trade statistics were adequate enough, mainly because their compilation was an administrative by-product. To be sure, various other statistical series were available in a regular form, some of them dating back to 1878, with varying degrees of sophistication and accuracy. However, the fact that any attempt at reconstructing reasonably satisfactory national income statistics before 1930 faced almost insurmountable difficulties is an indication of a serious gap in economic statistics as a whole.<sup>21</sup>

The termination of the war brought a new era in the compilation of statistics in Japan. Probably the most important was the deliberate forcing of the pace by the Occupation. For example, it was a matter of administrative necessity to have accurate statistics on such matters as crops, industrial production of all kinds, and price movements in grey and black markets. Thus the Occupation brought into Japan a special group of statistical experts headed by Dr. Stuart Rice—twice in five years (December 1946 and March 1951)—to advise the Japanese government in the task of modernizing the administrative structure and of improving methodology in relation to governmental statistical work in general. However, even before Dr. Rice came on his first visit, the Occupation administration, handicapped as it was by lack of qualified personnel, gropingly began the work of innovation in data-collecting and methodology. In this, there were factors, other than the policy orientation of the Occupation, which facilitated the undertaking. Over the decade preceding the end of the war, the small-sampling technique had made remarkable progress, and when the Occupation came, there were among the Japanese themselves a number of experts whose services could immediately be put to use. Probably more important, there had arisen in the immediate postwar period a strong and widespread interest among younger Japanese economists in econometric research of all kinds. For modern economists in particular, the erstwhile hold which "doctrinology" had over the profession was weakened. Economists like Miyoehei Shinohara and Shinichi Ichimura, as was mentioned earlier, led the younger group in the energetic application of new tech-

<sup>21</sup> There were exceptions to this rule. The most notable is the family expenditure survey which started in 1925 and was continued annually from 1930 to 1942. Initially, 7800 families were included in the sample, chosen mainly on a voluntary basis to report in detail their monthly expenditures in the prescribed accounting book.

niques to the mass of data pertaining to Japan which, at the outset, was inadequate and lean. The econometricians' enthusiasm and the statisticians' zeal started raising the level of both quality and quantity in the supply of economic statistics in Japan. It should also be mentioned in this connection that the publication of the first *Economic White Paper* in 1947 under the Katayama Cabinet started a kind of fashion among several economic ministries of issuing factual survey reports annually, and thus provided a further stimulus for the improvement and proliferation of statistical series compiled by government agencies. A so-called "White Paper" is now made public annually, not only by the Economic Planning Agency, which was the first, but also by the Ministry of International Trade and Industry, the Ministry of Labor, the Ministry of Agriculture and Forestry, the Ministry of Welfare, the Ministry of Transportation, as well as by specialized agencies within the Ministries, such as the National Income Unit of the Economic Planning Agency who published the *National Income White Paper*.

Once the Japanese became interested in statistics, it appears that there has been no stopping in the proliferation of such data. Through the legislative enactment of the Statistics Act of 1947, all the statistical activities of the government agencies came to be unified. A system of the "designated statistics" was established for important series on the one hand, and a system of compulsory reporting of other numerical facts to the Bureau of Statistics Standards on the other. Once a certain series becomes a "designated statistics," the agency concerned is empowered to make the filing by subjects obligatory and to enter the premises needed for the purpose; in turn, the agency must protect the confidential character of the filing by subjects and make public the results of the investigation as quickly as possible. As of September, 1959, there were on the official register altogether 57 sets of such "designated statistics," ranging from the population census to the nation-wide consumer behavior survey which is the latest addition. It will be too cumbersome to enumerate them all; but the list can be found in *Nihon Tōkei Hattatsu Shi* ("History of Development of Statistics in Japan"), 1960, compiled by the Nihon Tōkei Kenkyūsho ("Japan Statistical Research Institute"). As has been remarked by Shinohara, the econometrician with the most extensive knowledge of current economic statistics of Japan, the proliferation of statistical series has now reached a stage in Japan such that, even with the tremendously larger number of econometricians now at work as compared with prewar Japan, one finds it difficult to keep one's head above the deluge. The econometricians' complaint two decades ago has been answered by statisticians with vengeance.

This, however, is true only in so far as the current data are con-

cerned. As for the historical statistics, an attempt at radical improvement has been painfully slow. The work of compilation of what had already existed was naturally the first stage; and in this regard Yūzo Yamada's *Nihon Kokumin Shotoku Suikei Shiryō* ("Data Book for the Estimation of Japanese National Income Statistics"), first edition, 1951, was a pioneering work, that more by revealing the lacunae and limitations than by displaying positive results, acted as a stimulus for further research. This task was begun by the Institute of Economic Research, Hitotsubashi University, as a long-term project led mainly by Kazushi Ohkawa; and the work of digging out new data and of applying new methods to old data, altogether involving a most laborious and painstaking research activity, is still in progress. Interim results of the Ohkawa team, however, have been made public already in the form of *The Growth Rate of the Japanese Economy since 1878*, 1957; and Henry Rosovsky's *Capital Formation in Japan*, 1961, also may be considered, in a broad sense, as a product of the Ohkawa group. The Center for Japanese Economic Statistics at the Hitotsubashi Institute was recently established and studies of quantitative Japanese economic history will no doubt gain further momentum.
